hyperplasia has been characterized as a diffuse proliferation of clear cells in multiple glands, with little remaining normal tissue (Fig. 76-9). These criteria have proved totally unreliable. Although pathologic studies can usually distinguish parathyroid glands from other tissue, they may not prove useful beyond this capacity. Intraoperative decisions frequently depend on recognizing disease of one or more parathyroid glands, and in this regard, the histologic description of adenoma or hyperplasia is generally unreliable in primary hyperparathyroidism.²²

Patients with multiple-gland disease may have one gland that appears to be an adenoma and another that appears diffusely involved or even histologically normal with gross enlargement. The most reliable index of abnormality is the determination of glandular enlargement by visual inspection. The incidence of single- and multiple-gland enlargement as judged by visual inspection in 66 consecutive patients with hyperparathyroidism is shown in Table 76-9. The visual assessment and judgment of the experienced surgeon have proved to be an effective basis for intraoperative decisions. This approach requires that all four parathyroid glands be evaluated at the time of operation. However, the recent ability to rapidly measure PTH during operation has provided a method to assess gland function rather than size. This experience indicates that there may be more enlarged glands than there are hyperfunctioning glands.²³

Figure 76-9. Primary parathyroid hyperplasia. The normal adipose tissue of the gland has been replaced by sheets and trabeculae of hyperplastic chief cells.

Table 76-9 Gland Enlargement in 1,002 Consecutive Patients with Primary Hyperparathyroidism

Pathology	Patient, <i>n</i>	Percentage
Adenoma	788	78%
Double adenoma	98	9.8%
Hyperplasia	116	11.6%

From Hughes DT, Miller BS, Park PB, Cohen MS, et al. Factors in conversion from minimally invasive parathyroidectomy to bilateral parathyroid exploration for primary hyperparathyroidism. *Surgery* 2013;154(6):1428–1434.

Carcinoma

Parathyroid carcinoma is a rare entity, and the histologic diagnosis can be exceedingly difficult. The surgeon may suspect the diagnosis when dense invasion and scarring are encountered, although this may also be secondary to some other inflammatory disease in the neck. Pathologic criteria include marked mitotic activity, dense fibrous stroma, and evidence of local invasion into the capsule or surrounding vessels.²⁴ Malignant-appearing tumors, however, may pursue an apparently benign clinical course; the converse is less frequently true. The only reliable criteria of malignancy are metastases, most commonly to the lymph nodes, lung, or liver, and true local invasion.

Systemic Effects

The use of automated technology for determining serum calcium has changed not only the estimated incidence of hyperparathyroidism but also the usual mode of presentation. Before screening, three-fourths of patients presented with renal disease, particularly nephrolithiasis; one-third to one-half had skeletal manifestations, and rare patients had both. Most recent series suggest that at least half of the patients in whom hyperparathyroidism is diagnosed do not have renal or osseous disease and many are minimally symptomatic or asymptomatic. Manifestations of the disease are protean but generally

nonspecific, and they may be difficult to elicit in the history. A significant proportion of patients present without a readily quantifiable index of disease severity. This finding has created some controversy about the need for surgery in the asymptomatic patient and particularly for the elderly or high-risk patient.^{18,25}

The earliest complaints are often the vague symptoms of hypercalcemia. These vary with the magnitude of plasma calcium elevation and can include muscle weakness, anorexia, nausea, constipation, polyuria, and polydipsia. These nonspecific symptoms may or may not cause the patient to seek medical attention. Some symptomatic patients have evidence of chronic disease involving the kidney or skeleton. Usually, only one of these systems is significantly involved in any individual patient. The treatment of hyperparathyroidism is designed to eliminate or halt the progression of the complications of the disease. Symptomatic patients can be divided into two groups. Members of the first group have renal manifestations, a slower onset of symptoms, and generally lower serum calcium concentrations. Patients in the second group have a more rapid onset of symptoms, higher serum calcium levels, and significant bone disease. No recognizable histologic or physiologic characteristics distinguish patients with renal disease from those with bone disease.

Figure 76-10. Abdominal film demonstrating nephrocalcinosis, or diffuse calcification of the renal parenchyma (*arrows*).

Renal Manifestations

Renal complications develop because the hypercalcemia leads to an increase in urinary calcium excretion and because PTH increases the excretion of phosphate and produces urinary alkalosis. Both these events predispose to stone formation. Urinary stones can be treated surgically or with lithotripsy, and subsequent definitive treatment of the hyperparathyroidism reduces the rate of reformation. Of patients who present for the first time with renal colic, 5% to 10% are found to have primary hyperparathyroidism. Nephrocalcinosis ([Fig. 76-10](#)) is calcification of the renal parenchyma and occurs in 5% to 10% of patients with hyperparathyroidism. It causes more significant renal damage than nephrolithiasis does. In general, the more severe the renal damage, the less likely it is that nephrocalcinosis will regress after parathyroidectomy.

The incidence of hypertension in hyperparathyroidism increases with the degree of renal impairment. Hypertension may be a significant cause of the morbidity associated with hyperparathyroidism, but although a decrease in blood pressure has been demonstrated in some patients after parathyroidectomy, the correlation between the two conditions is not clear.

Skeletal Manifestations

Parathyroid bone disease in its most classic and severe form, osteitis fibrosa cystica, is seldom encountered; however, 5% to 15% of patients with parathyroid bone disease present with significant symptoms of skeletal disease. Most commonly, these symptoms include bone pain and pathologic fractures.

Bone changes are often demonstrable on detailed plain radiographs of the hands ([Fig. 76-11](#)). Characteristically, subperiosteal resorption is evident on the radial aspect of the middle phalanx of the second or third finger. Because of tufting of the distal phalanges, clubbing may be evident on physical

examination. Other findings that typically involve the skull and long bones include bone cysts, “brown” tumors (i.e., localized proliferations of osteoclasts), and diffuse demineralization or granularity. More subtle bone loss can be detected by iliac crest bone biopsy or dual energy x-ray absorptiometry scan. The risk of bone fracture increases with increasing severity of bone loss.

Figure 76-11. Magnification radiograph of the fingers in hyperparathyroidism. Subperiosteal cortical resorption (*arrows*) typically is most visible on the radial aspect of the middle phalanges.

Gastrointestinal Manifestations

Hypercalcemia is clearly associated with nonspecific gastrointestinal complaints, including nausea, vomiting, constipation, and anorexia, but attempts to demonstrate a definite relation between hyperparathyroidism and either peptic ulcer disease or pancreatitis remain unconvincing. Hypercalcemia stimulates gastric acid secretion experimentally and clinically, and has been associated with pancreatitis. Therefore, a theoretic rationale for the complex of hyperparathyroidism and gastrointestinal symptoms does exist.

Neuromuscular Manifestations

Neurologic and muscular complaints are those of hypercalcemia in general. Fatigability and proximal muscle weakness are among the most debilitating manifestations. Atrophy of type II muscle fibers, consistent with a neuropathic and not a myopathic cause, has been demonstrated. Sensory complaints include dysesthesia, a reduced vibratory sense, and stocking–glove sensory deficits.

Psychological Manifestations

The emotional disturbances of hyperparathyroidism are often subtle and difficult to quantify. As with other forms of hypercalcemia, they range from depression or anxiety to psychosis and coma. Patients undergoing parathyroidectomy frequently experience a sense of well-being and relief from fatigue and dullness postoperatively, even if they may have had no noticeable complaints preoperatively.

Other Manifestations

A variety of signs and symptoms of soft tissue calcification have been described. Nonspecific arthralgia, particularly involving the proximal interphalangeal joints of the hands, is characteristic. The incidence of chondrocalcinosis is increased. Pruritus, vascular and cardiac calcification, and band keratopathy of the cornea have all been noted. Some reports have suggested an increased risk of malignancy and coronary artery disease, but the effects remain unsubstantiated, and it is not clear if the mortality risk is modifiable by correction of hyperparathyroidism.^{26–28}

Physical Findings

Except in patients with the classic deformities of advanced bone disease, the physical examination is seldom helpful. Diseased parathyroid glands are infrequently palpable, except in patients with parathyroid carcinoma. A mass in the anterior neck in a patient with primary hyperparathyroidism is most commonly a thyroid nodule.

Laboratory Findings

Tests for calcium, PTH, phosphate, bicarbonate, and magnesium, in addition to other laboratory tests, are useful to establish the diagnosis of hyperparathyroidism.

Calcium. Hypercalcemia is the single most important diagnostic finding; however, particularly in early or mild cases, serial analysis may show fluctuations in and out of the normal range. Coexistent hypoalbuminemia and acidosis may produce an apparently normal total serum level of calcium, even though the ionized fraction is actually elevated. Serum concentrations of ionized calcium may be helpful in the patient with intermittent or mild hypercalcemia.

3 Parathyroid Hormone. PTH measurement is an important method for establishing the diagnosis of hyperparathyroidism. Because of the heterogeneity of the various circulating forms of PTH, measurement of C-terminal or N-terminal fragments give conflicting and confusing results. Intact hormone assays and whole molecule assays are the most dependable. The demonstration of an elevated plasma PTH concentration alone does not establish the diagnosis of hyperparathyroidism. With a simultaneous elevated serum calcium level, this finding is virtually diagnostic ([Fig. 76-12](#)).

Phosphate. PTH increases renal phosphate excretion and, in about half of patients, produces hypophosphatemia. In the presence of renal disease, however, the serum phosphate levels may be normal or significantly elevated.

Bicarbonate. PTH also increases bicarbonate excretion, so that a hyperchloremic metabolic acidosis may develop. It has been suggested that the finding of an elevated serum chloride-to-phosphate ratio may be helpful in the differential diagnosis of hypercalcemia. A ratio greater than 30 is considered highly suggestive of hyperparathyroidism.

Magnesium. Hypomagnesemia develops in 5% to 10% of patients with hyperparathyroidism. After parathyroidectomy, if both hypocalcemia and hypomagnesemia are present, it may be difficult to correct the calcium until the serum magnesium has been corrected.

Other Diagnostic Tests. A variety of special diagnostic tests for hyperparathyroidism are available. None is more specific than the measurement of serum concentrations of calcium and PTH, although they may be useful in equivocal cases. For example, the 24-hour urinary calcium excretion is usually elevated, but may be normal, in patients with hyperparathyroidism, although the finding is not specific for this disease. This test is helpful in identifying patients with familial hypercalcemic hypocalciuria, in whom the rate of urinary calcium excretion is low. Measurements of tubular reabsorption of phosphate below 30% suggest primary hyperparathyroidism. Urinary cAMP is generated specifically as a consequence of PTH activation of renal tubular adenyl cyclase. Increased urinary concentrations are identified in most patients with primary hyperparathyroidism. These measurements are rarely necessary because of the reliability of the intact PTH measurement.

Localization with Imaging Techniques

In order to try to simplify the operative approach to hyperparathyroidism, an attempt is usually made to localize enlarged glands preoperatively. In the hands of an experienced surgeon, the cure rate for hyperparathyroidism at the initial operation without preoperative localization exceeds 95% with the conventional full-neck exploration. However, technologic developments have led surgeons to pursue alternatives to the full-neck exploration. These innovations are increasingly accurate preoperative localization with ^{99m}technetium sestamibi scintigraphy, computed tomography scans with carefully timed intravenous contrast administration, or high-resolution ultrasound, combined with intraoperative intact PTH measurement that allows termination of the operation without visualization of all four parathyroid glands. Surgeons have used these technologies in various combinations to limit the extent of the neck exploration. All of the current alternative strategies, however, depend on a preoperative parathyroid localization study to direct the exploration.

Figure 76-12. Relation between serum immunoreactive parathyroid hormone and serum calcium in patients with hypoparathyroidism, pseudohypoparathyroidism, ectopic hyperparathyroidism, and primary, secondary, and tertiary hyperparathyroidism. GP1M, guinea pig antiserum 1M.

Figure 76-13. ^{99m}Tc sestamibi scan of a patient with a parathyroid adenoma. The radionuclide is present in both thyroid and parathyroid tissues on the 10-minute film; however, by 2 hours, the radionuclide has washed out of the thyroid and remains only in the right-sided parathyroid gland. This scan shows a 794-mg right upper parathyroid adenoma (arrow).

The study most frequently used for imaging previously unoperated patients is ^{99m}Tc sestamibi scintigraphy (Fig. 76-13). Sestamibi scanning can identify the site of abnormal tissue in 75% to 80% of patients but has limitations in patients with small adenomas or multiple-gland disease. Sestamibi was originally developed for cardiac imaging. The use of a single nuclide with a short half-life and a high-energy profile has advantages in lateral, oblique, and three-dimensional imaging that technetium–thallium scanning, which was formerly used, does not provide.

High-resolution ultrasound examination of the neck is also used for localization of abnormal parathyroid tissue, particularly when it is available for use by the clinician. The current machines scan at high frequencies (10 to 13 MHz) that allow demonstration of small abnormalities in the neck (Fig. 76-14). The examination is best done by a clinician in real time, as that allows the most complete assessment of the neck, rather than scans performed by a technician for later review of still pictures by the physician. The sensitivity of cervical ultrasound for abnormal parathyroid glands is about the same as for sestamibi scanning. Ultrasonography is an operator-dependent technique. It is rapid and relatively inexpensive and can direct fine-needle aspiration for cytologic confirmation and immunoassay for PTH.

In patients with persistent or recurrent hyperparathyroidism, preoperative imaging is important to guide the exploration. High-resolution real-time ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), and sestamibi scanning all appear to have comparable sensitivities of 50% to 60%. The results of these examinations may be less successful at centers without significant experience in their use.

Computed tomography is more expensive but less operator-dependent than ultrasonography. It clearly is superior in identifying deeper structures and for examining the retrosternal mediastinum. MRI is considerably more expensive than CT and has not been shown to be superior. Most surgeons prefer to have results of two or more imaging tests that confirm an abnormality before exploration in the reoperative setting.²⁹

Treatment

Indications for Surgery

Generally, the only practical therapeutic option is surgery. Nephrolithiasis, bone disease, and

neuromuscular symptoms all respond well to surgical intervention. In contrast, surgery in patients with renal failure, hypertension, and psychiatric symptoms is not so uniformly successful, although it benefits some patients and is usually indicated in all except those at highest risk. The question of how to manage the large group of patients with apparently asymptomatic disease requires particularly careful consideration.

Management of Asymptomatic Hyperparathyroidism

4 A large proportion of patients with the diagnosis of hyperparathyroidism are minimally symptomatic or asymptomatic. The appropriate treatment for these patients remains controversial. Although little evidence indicates that irreversible complications, such as renal failure, eventually develop in patients with asymptomatic mild disease, the natural history of the disease remains incompletely defined. Many of the manifestations of this disease may go unrecognized until they are corrected surgically. Still unanswered is the question of how much asymptomatic disease may contribute to generalized osteopenia in this predominantly postmenopausal female population.

Figure 76-14. Ultrasound views of parathyroid adenomas. **A:** Sagittal image of the upper pole of the right lobe of the thyroid gland, demonstrating a hypoechoic parathyroid adenoma posterior to the thyroid parenchyma. **B:** Sagittal image of the lower pole of the left lobe of the thyroid gland with an adjacent hypoechoic parathyroid adenoma measuring 9 mm in greatest dimension.

Table 76-10 Indications/Contraindications

National Institutes of Health Consensus Development Conference's Indications for Surgical Intervention in Patients with Asymptomatic Primary Hyperparathyroidism	
■	Markedly elevated serum calcium (>1.0 mg/dL above normal)
■	History of an episode of life-threatening hypercalcemia
■	Reduced creatinine clearance
■	Presence of one or more kidney stones detected by abdominal radiography
■	Markedly elevated 24-hr urinary calcium excretion
■	Substantially reduced bone mass as determined by direct measurement (dual energy x-ray absorptiometry T-score ≤-2.5)

A recent report detailed the 15-year natural history of 116 patients with asymptomatic hyperparathyroidism.¹⁸ Operation was recommended for those in whom symptoms or findings developed, according to the guidelines of the National Institutes of Health Consensus Conference (see later). During the monitoring period, 51% of the patients had operation, and biochemical normalization and increased bone mass were observed in those who underwent surgery. However, the patients who did not undergo operative correction continued to have biochemical abnormalities and the cortical bone mass fell significantly. These data confirm the impression of most clinicians that mild hyperparathyroidism rarely takes a precipitously worsening clinical course; however, the differential bone effects that are evident by 15 years call into question how long such patients can be monitored without correction.

In October 1990, a National Institutes of Health Consensus Development Conference reviewed the

available evidence regarding the management of asymptomatic primary hyperparathyroidism.³⁰ After interval developments, a panel of experts reconvened in 2002, and revisited this issue.³¹ The panel agreed that operation is the indicated treatment for all patients with symptoms; however, they recognized a subgroup of patients who have no symptoms attributable to hyperparathyroidism, and their conclusions included several indications for surgical intervention in these asymptomatic patients (Table 76-10).

The panel mandated close (every 6 months) follow-up for those patients not treated by operation. In addition, they recommended surgery for cases in which medical surveillance is neither desirable nor suitable, such as when a patient requests surgery, consistent follow-up is unlikely, coexistent illness complicates management, or a patient is younger than age 50 years.

This remains an area of considerable controversy, and subsequent reviews have supported similar plans with only minor revisions.^{32,33} The complication rate of operation by an experienced surgeon is very low. Within a short period, the financial cost of medical follow-up exceeds that of treatment by operation. Based on these considerations, most patients should undergo operation, and those who do not must be closely followed.

Principles of Surgical Correction

Although neck exploration for hyperparathyroidism may be straightforward, it sometimes becomes an arduous procedure requiring considerable patience because of the variability in both the location and the number of diseased glands. Persistent hyperparathyroidism and the necessity for reexploration can usually be avoided by a meticulous initial procedure. Reoperation is predictably more difficult than the initial operation, and the risks for damage to the recurrent laryngeal nerves and hypoparathyroidism are greater during reoperation.

It is essential that the surgeon be confident of the preoperative diagnosis and prospectively discuss the procedure with the patient. The potential complications of damage to either the recurrent laryngeal nerve or the superior laryngeal nerve and the development of hypocalcemia require discussion. Likewise, the possibility of an unsuccessful initial operation must be explained, and the patient should recognize that reexploration, including median sternotomy, may be required. Although alternatives to full-neck exploration are often now applied, no patient should be explored by a surgeon who is unfamiliar with the principles and techniques of the conventional full-neck exploration.

For a full-neck exploration, the patient is placed under general anesthesia with a roll beneath the shoulders and the neck extended. The neck is opened through a transverse incision overlying the thyroid isthmus, and the platysma is similarly divided. Superior and inferior flaps are developed. The strap muscles are separated in the midline and retracted laterally; division is unnecessary. One lobe of the thyroid is chosen and rotated medially. Important landmarks include the tracheoesophageal groove, the recurrent laryngeal nerve, the inferior and superior thyroid arteries, and the middle thyroid vein (Fig. 76-15). In most patients, the nerve lies in the tracheoesophageal groove or just laterally. Occasionally, it may be situated more anteriorly. Uncommonly, it may originate directly from the vagus without passing around the right subclavian artery. Both of these latter variations make the recurrent nerve more susceptible to injury. The external branch of the superior laryngeal nerve, which innervates the cricothyroid muscle, usually lies medial to the superior thyroid vessels and should be carefully preserved.

Figure 76-15. Lateral view of the right side of the neck after rotation of the thyroid lobe. The important anatomic landmarks are

For a full-neck exploration, all four glands should be identified at the initial exploration because of the possibility of multiple-gland disease. Supernumerary glands may be present and should be sought at the initial procedure. Although a frozen section has not been helpful in differentiating diseased from normal glands, it is generally reliable for confirming the presence or absence of parathyroid tissue. Small, thin biopsy specimens are sharply incised from the gland, with extreme care taken to avoid damaging its delicate blood supply. Most surgeons use a frozen section selectively to confirm suspected abnormal parathyroid tissue or to document difficult or confusing situations.³⁴

The upper glands are usually located far dorsally on the surface of the thyroid lobe at the level of the upper two-thirds of the gland. The lower glands are less constant and may be located anywhere from well above the thyroid to the anterior mediastinum. The lower glands are most typically in the region where the thyrothymic ligament attaches to the lower pole of the thyroid lobe. If the inferior glands cannot be localized, the thymic pedicle should be carefully examined and mobilized. Because of their common embryologic origin, the inferior gland is frequently associated with the thymic remnant. Parathyroid glands within the mediastinum sometimes can be removed by mobilizing the thymus through the cervical incision. If this technique is unsuccessful in identifying the parathyroid gland, the thyroid lobe on the side of the missing gland is mobilized and palpated. Intraoperative ultrasonographic examination may identify an intrathyroidal parathyroid gland. As a last resort, excision of the thyroid lobe may be indicated.

If after meticulous exploration of all these areas three or four parathyroid glands have been identified, none of which is enlarged, most surgeons favor terminating the operation.

Limited Surgical Exploration

5 With the availability of accurate preoperative localization methods, it has become routinely possible to identify abnormal parathyroid glands prior to operation for most patients. This allows the surgeon to know where to start the exploration. Then, intraoperative PTH measurement can be used to confirm removal of all hyperfunctioning parathyroid tissue, that is, when to stop the operation. This strategy of directed, limited neck exploration is applicable to about 75% of initial parathyroid explorations, and has about the same success rate as full-neck exploration.^{35–37} The preoperative localization can be done by either ^{99m}technetium sestamibi nuclear medicine scan or by high-resolution ultrasound. The intraoperative PTH measurement is first assessed at the outset of the procedure, and/or immediately preceding parathyroid gland excision (the preexcision baseline). Blood samples are obtained at time intervals after parathyroid gland resection. A decrease of the PTH level by 50% from the higher of the incision or pre-excision baseline predicts long-term normocalcemia.³⁸ Other investigators use more sensitive criteria for the detection of multigland disease, including reduction of the PTH level into the normal range and kinetic assessments of the rate of PTH decrease.³⁹ This increase in sensitivity comes with the cost of decreased specificity, however. Blood samples can be obtained either centrally or peripherally.⁴⁰

The limited nature of this operative approach also makes it easier to perform this operation under regional or local anesthetic in an ambulatory setting. However, because of the possibility of multiple gland disease or inaccurate preoperative localization, all surgeons undertaking this approach should also be skilled in the full-neck exploration for hyperparathyroidism.^{41–43}

Extent of Resection

The operative procedure performed has been based on the number of enlarged glands identified at full-neck exploration; however, with the use of intraoperative PTH monitoring, it has become clear that not all enlarged parathyroid glands are hyperfunctioning.⁴⁴ In contrast, nearly all hyperfunctioning glands are enlarged and hypercellular. The full-neck exploration experience has demonstrated that removing all enlarged glands is a highly successful approach to curing hyperparathyroidism. In the absence of PTH monitoring, this remains an accepted approach. Typically, single-gland disease has been treated by simple excision, whereas any combination of two- or three-gland enlargement is treated by resecting the diseased tissue and leaving the normal glands in place. The question of whether two- or three-gland enlargement implies the presence of disease in all glands (hyperplasia) has not been resolved. If one gland is large and the remaining three are normal in size, resection of the single parathyroid cures virtually all patients. Of 76 patients with two- or three-gland disease treated by excising the large glands and leaving the normal glands, only eight (10.5%) had recurrent hypercalcemia, which tended to

be mild (follow-up of 12 to 140 months postoperatively). This approach seems satisfactory in most patients.⁴⁵

Treating patients with four-gland disease has been more difficult. In many of these patients, the disease occurs as a component of one of the familial syndromes, particularly MEN-1. Patients with four-gland parathyroid disease can be treated by subtotal parathyroidectomy (removing three and a half glands) or by total parathyroidectomy with autotransplantation of some parathyroid tissue into the nondominant forearm. Both operations depend on meticulous identification of all parathyroid tissue for adequate results. The putative advantage of the subtotal parathyroidectomy is that it leaves the remaining parathyroid tissue with its native blood supply. Total parathyroidectomy with autograft has the advantage of removing all the abnormal parathyroid tissue from the neck and placing it in a site where reoperation for recurrent hyperparathyroidism is simpler. Over time, subtotal parathyroidectomy has become the more common approach.

The reported incidence of recurrent hypercalcemia after subtotal parathyroidectomy for nonfamilial parathyroid hyperplasia is 0% to 16%; the incidence of permanent hypoparathyroidism is 4% to 5%. Total parathyroidectomy with autograft is associated with a similar risk for permanent hypoparathyroidism in the sporadic setting (5%) and a higher reported risk for recurrent hypercalcemia (20%). Reoperation for recurrent hypercalcemia is simplified by the approach of total parathyroidectomy with autotransplantation. Thus, given the current data, sporadic parathyroid hyperplasia can be acceptably treated by either operation. In patients with MEN-1, the disease is not the same as sporadic hyperplasia. Rather, defects in the MEN-1 gene cause multiple parathyroid adenomas that arise independently over the life of the patient.²¹ The operative results reflect this independent capability of all parathyroid tissue in these patients to become neoplastic. The hypercalcemia recurrence rate is 26% to 36% with long-term follow-up after subtotal parathyroidectomy, and similar after total parathyroidectomy with autograft. However, the incidence of permanent hypoparathyroidism after autograft in MEN-1 is also significant (reported as high as 46%). While both approaches are currently accepted, most experienced centers now advocate subtotal parathyroidectomy as the initial operation in MEN-1 hyperparathyroidism, and anticipate that recurrent disease is likely, manageable, and less problematic than permanent hypocalcemia.^{46,47}

Technique of Parathyroid Autotransplantation

The parathyroid gland is sliced into 15 to 20 pieces and autografted into a forearm muscle bed. The sites are marked with silk sutures. This location permits easy subsequent access under local anesthesia if recurrent hypercalcemia develops. Function of the autograft is documented by (a) normocalcemia, with the autograft as the only source of PTH, (b) by measuring higher concentrations of hormone in the antecubital vein draining the graft bed than in the corresponding vein in the opposite arm, or (c) “transient parathyroidectomy,” by placing a venous occlusive tourniquet on the arm above the graft, and measuring changes over several minutes in the PTH levels drawn from the contralateral arm.⁴⁸ Lack of function is unusual outside of the MEN-1 patients; hypoparathyroidism develops in about 5% of patients. Glands can also be cryopreserved in dimethyl sulfoxide and serum. If in the postoperative period it becomes clear that the patient is aparathyroid, the cryopreserved tissue can be reimplanted under local anesthesia.

Special Situations

Persistent or Recurrent Hyperparathyroidism

Persistent hyperparathyroidism occurs in fewer than 5% of patients after exploration by an experienced surgeon. Most commonly, it is the result of a single diseased gland remaining in the neck or the mediastinum. Recurrent disease develops after an interval of normocalcemia and may be the result of regrowth of diseased tissue, implantation from a tumor broken at the initial procedure, or recurrent parathyroid carcinoma.

In the evaluation of these patients, it is essential to document that the initial diagnosis was correct. Familial hypocalciuric hypercalcemia should be excluded by measuring urinary calcium excretion.

Reviewing the original operative notes and pathology reports may provide clues to the position of missed glands. The locations of parathyroid tumors not found at the initial operation but identified on subsequent exploration in one large series are shown in [Figure 76-16](#).

It is generally agreed that localization studies do have a place in the management of recurrent disease. Noninvasive methods are used first, and if these are unsuccessful in identifying the diseased gland, selective angiography and venous sampling for PTH are used. The utility of the techniques vary

across institutions, dependent on local experience, expertise and preference. Selective angiography localizes 50% to 80% of parathyroid glands that cannot be detected by any other modality. Venous sampling may also be helpful in some patients, although interpretation can be complicated by the collateralization that occurs postoperatively. Because it provides no direct image but indicates the side and level of the neck where the hyperfunctioning tissue is located, it may help to direct the evaluation of imaging studies and the exploration to one or the other side of the neck. Both these invasive radiographic techniques require considerable expertise. Transient cortical blindness, transverse myelitis, and cerebrovascular accidents have all been reported as complications of arteriography. Angiographic ablation of mediastinal parathyroid tissue with large doses of ionic contrast has been successful in selected patients. This technique may be used in some patients with mediastinal parathyroid adenomas who are at increased surgical risk and who have other functional parathyroid tissue remaining.⁴⁹

Figure 76-16. Location of parathyroid tumors missed on initial exploration but identified on subsequent operation.

Surgical reexploration can be a difficult procedure. The neck should almost always be reexplored first. If the thymic remnant has not already been removed, it should be excised at this time. Two adjunctive techniques, intraoperative ultrasonography to locate glands and intraoperative measurement of PTH to document the adequacy of resection, may be useful in patients undergoing operation for persistent disease.²⁹

If the gland is not identified in the neck by means of the maneuvers described, the mediastinum is examined; most surgeons do this only if there is imaging evidence of disease in the mediastinum, rather than unguided exploration. Median sternotomy and exploration are necessary in only 1% to 2% of patients with hyperparathyroidism. Successful transcervical mediastinal exploration is sometimes possible with use of the Cooper thymectomy retractor, a substernal retractor that permits more extensive mediastinal exploration and thymectomy through a cervical incision.⁵⁰ Any remaining thymic tissue is first isolated and examined. Inferior parathyroid glands most commonly migrate into the anterior mediastinum. If the results of this exploration are negative, the area posterior and lateral to the trachea is then explored. The location of superior parathyroid glands may be as far posterior as the esophagus and as far superior as the pharynx.

Surgical reexploration is successful in experienced hands in about 80% of cases. The incidence of complications is increased. Unilateral recurrent nerve injury occurs in 5% to 10% of patients postoperatively, and permanent hypoparathyroidism in 10% to 20% of patients. Cryopreservation of excised tissue may be included as a component of the management of these patients because it allows later autotransplantation if the patient becomes hypoparathyroid postoperatively. However, the demonstration of continued PTH production by intraoperative PTH measurement makes cryopreservation unnecessary. The risks of these complications must be clearly outweighed by the clinical improvement in patients with advanced disease. Reoperation in asymptomatic patients with mild disease is controversial.

Hypercalcemic Crisis

Occasionally, patients with hyperparathyroidism become acutely hypercalcemic with severe symptoms. The pathogenesis appears to involve a cycle of uncontrolled PTH secretion followed by hypercalcemia and secondary polyuria, dehydration, and reduced renal function, which exacerbate the hypercalcemia. Serum calcium concentrations may reach 16 to 20 mg/dL, and the syndrome is manifested by rapidly

developing muscle weakness, nausea and vomiting, lethargy, fatigue, and even coma. Ultrasonography, sestamibi scan, or CT scan may help to identify the enlarged gland to allow expedient correction.

Definitive treatment involves resecting the diseased parathyroid tissue, which is almost always curative. Generally, however, it is safer to lower the serum calcium level before operation.

Hyperparathyroidism in Pregnancy

Hyperparathyroidism in pregnancy is a rare disorder that not only causes hypercalcemia in the mother but also is associated with increased morbidity and mortality rates in the fetus. Even the newborn is at risk for the development of tetany. The risk for fetal complications is higher if the hyperparathyroidism is left untreated. The mother should undergo operation in the second trimester,⁵¹ though the outcome for the pregnancy with modern management is good overall.⁵²

Neonatal Hyperparathyroidism

Neonatal hyperparathyroidism occurs in infants who are homozygous for a mutation of the calcium-sensing receptor and is characterized by hypotonia, poor feeding, constipation, and respiratory distress. Each parent of these children is affected by familial hypocalciuric hypercalcemia. The 1-year survival rate in children with symptoms is less than 50%, and patients without symptoms appear to have significant bone disease. Total parathyroidectomy with autotransplantation is the treatment of choice.⁵³

Secondary Hyperparathyroidism

Secondary hyperparathyroidism develops as a consequence of chronic renal failure. Phosphate retention and hyperphosphatemia reduce the serum calcium levels. This effect is aggravated by the reduction in 1-hydroxylase activity in the kidney, necessary for the activation of vitamin D₃. The secondary increase in PTH levels to compensate for the hypocalcemic effects is exacerbated by aluminum accumulation in bone. Aluminum, present both in the dialysate fluid and in phosphate-binding medications, contributes to the osteomalacia (renal osteodystrophy) that develops in all these patients after several years of dialysis. Therapy includes controlling the hyperphosphatemia with dietary restriction and phosphate-binding gels, calcium supplementation orally and in the dialysate bath, correction of acidosis, administration of vitamin D sterol, and reduction in aluminum intake in both the dialysate and the diet. Therapy should be initiated carefully because metastatic soft tissue calcification can occur. Indications for surgical therapy include persistent, symptomatic hypercalcemia that cannot be controlled medically, particularly in prospective renal transplant patients; bone pain and abnormal fractures; ectopic calcification; and intractable pruritus. Subtotal parathyroidectomy and total parathyroidectomy with heterotopic autotransplantation both appear to be acceptable options, although reexploration for recurrent disease is less complicated after total parathyroidectomy with autotransplantation. Parathyroidectomy can enhance aluminum deposition, so any excess should be corrected preoperatively through chelation.

Parathyroid Carcinoma

Parathyroid carcinoma is a rare condition, accounting for less than 1% of all cases of hyperparathyroidism. Histologic criteria remain controversial, and the diagnosis is securely made only on the basis of local invasion or distant metastases. In comparison to patients with benign disease, these patients tend to be somewhat younger and more symptomatic. In contrast to the marked female predominance in benign disease, the male-to-female ratio in carcinoma is equal. Serum calcium, PTH, and alkaline phosphatase levels are relatively more elevated, and patients often have an elevated level of human chorionic gonadotropin. Patients may have manifestations of both renal and bone diseases. The affected gland is palpable in almost half of patients.

Initial treatment should include radical resection of the involved gland, ipsilateral thyroid lobe, and regional lymph nodes. Neither chemotherapy nor radiation therapy has shown any benefit. If the disease recurs, resection should be attempted because without treatment these patients usually succumb to uncontrolled hypercalcemia. The long-term prognosis is poor, and the opportunity for survival depends on complete initial resection.^{24,54}

MULTIPLE ENDOCRINE NEOPLASIA

Although these familial disorders are typically characterized by a predisposition to the development of tumors of multiple endocrine organs, the parathyroid is characteristically involved in two of them. The disorders are all inherited in an autosomal dominant fashion, and the tumors tend to be multicentric.

The tumors can be benign or malignant and can occur metachronously or synchronously. MEN-1 is characterized by the concurrence of parathyroid hyperplasia, pancreatic islet-cell tumors, and pituitary adenomas. MEN-2A consists of medullary thyroid carcinoma (MTC), pheochromocytoma, and parathyroid hyperplasia. MEN-2B includes MTC, pheochromocytoma, mucosal neuromas, and a distinctive marfanoid habitus. Together these syndromes encompass much of the spectrum of endocrine neoplasia.

Pathogenesis

The genetic abnormality in MEN-1 has been identified and described in detail.^{55,56} As a tumor-suppressor gene, the first mutation is inherited and becomes unmasked only when a second mutation, in some cases a deletion, develops in susceptible tissues. The resulting complete loss of the tumor suppressor allows neoplasia to develop. The occurrence of multiple second mutations explains the characteristic multicentric involvement of these diseases. Direct genetic testing is now available for some families with known mutations.

Mutations of the *RET* protooncogene are the cause of MEN-2A.^{57,58} Genetic testing is now available to identify affected family members and provide the opportunity for early treatment of MTC in affected persons.

Clinical Features and Management of Multiple Endocrine Neoplasia Type 1

Characteristically, MEN-1 presents in the third and fourth decades, without any gender predilection.⁵⁹ The syndrome is expressed with nearly complete penetrance, and autopsy studies suggest that all three organs are affected in more than 90% of patients. The phenotype varies, however; more than 90% of patients have hyperparathyroidism, but evidence of islet cell neoplasms (30% to 80%) and pituitary tumors (15% to 50%) is less common. The cause of death in carriers of the MEN-1 mutation is related to MEN-1 in about 45% of patients and often caused by malignant islet cell or carcinoid tumors.⁶⁰

Parathyroid Disease

Hypercalcemia secondary to hyperparathyroidism is usually the first biochemical abnormality detected in MEN-1 and represents the best screening opportunity for members of affected kindreds until direct genetic screening is available in a specific family. Many of these patients are asymptomatic and have relatively mild hypercalcemia. When symptoms do develop, they typically involve the urinary tract rather than the skeleton.

Typically, the patients have four-gland disease, which may be particularly difficult to manage. The disease is characterized by metachronous development of multiple parathyroid adenomas. There is no curative operation; the two accepted approaches (subtotal parathyroidectomy and total parathyroidectomy with autograft) each have faults (see earlier). Over time, the subtotal parathyroidectomy approach is becoming the preferred choice by most surgeons.

Figure 76-17. Scatter plot of largest primary tumor size versus metastatic status in 43 patients with pancreatic islet cell tumors associated with multiple endocrine neoplasia type I. Each point represents a single patient. Tumor size is not correlated with the presence of liver or lymph node metastases. (From Lowney JK, Frisella MM, Lairmore TC, et al. Islet cell tumor metastasis in multiple endocrine neoplasia type I: correlation with primary tumor size. *Surgery* 1998;124:1043–1049.)

Pancreatic Tumors

In patients with pancreatic tumors, multicentric and diffuse hyperplasia of the pancreatic islets may occur in areas distant from any grossly evident tumor. The management of these tumors is controversial because although some patients have aggressive, malignant tumors, many patients have a fairly benign

course. No reliable criteria are available to detect malignant tumors. Tumor size is often cited as a useful marker of prognosis, but substantial overlap has been noted between the sizes of primary benign and malignant tumors (Fig. 76-17).⁶¹ Because of the difficulty in identifying the more aggressive subset, some authors have chosen a liberal policy of early operation to try to prevent metastasis and death. Pancreatic tumors are typically multicentric and frequently malignant. Somatostatin receptor scintigraphy can be a useful imaging technique to demonstrate the extent of tumor (Fig. 76-18).⁶²

Figure 76-18. Somatostatin receptor scintigraphy in a patient with multiple endocrine neoplasia type I. This scintiscan detected an otherwise unrecognized metastasis to the left lateral segment of the liver (*white arrow*), which was resected along with the small primary tumor (*black arrow*).

Gastrinoma is the most common functional tumor in MEN-1; typically, a severe ulcer diathesis (Zollinger–Ellison syndrome) develops that is associated with secretory diarrhea. Serum gastrin levels are usually markedly elevated ($>1,000$ pg/mL); when levels are equivocal (250 to 1,000 pg/mL), provocative testing with secretin (2 m/kg) may be useful. An absolute serum gastrin increase of 200 pg/mL is diagnostic. The primary tumors are often in the submucosa of the duodenal wall.

Biochemical cure of these gastrinomas is almost never possible, which is different than patients with sporadic gastrinomas, although exploration can reduce the need for antisecretory medications and may reduce the risk for liver metastasis. Histamine 2-receptor antagonists or proton pump inhibitors are effective in controlling acid secretion, although very high doses may be necessary; the malignant disease is often indolent. Total gastrectomy is no longer ever necessary to eliminate acid secretion.

Insulinoma is the next most common functional pancreatic neoplasm in MEN-1. Patients present with a history of sweating, dizziness, confusion, and syncope, consistent with neuroglycopenia; these symptoms are relieved by consuming carbohydrates. The diagnosis is verified by documenting fasting hypoglycemia associated with inappropriately elevated plasma insulin levels. Preoperative tumor localization is usually achieved by a combination of CT and arteriography. Calcium is injected into various pancreatic arteries and plasma insulin levels in the hepatic vein plasma are measured to detect a gradient after the injection of specific pancreatic arteries localizing the area of the pancreas containing the functional tumor.

Because the available medical therapy for insulinoma is limited, patients are treated operatively. Lesions in the tail of the gland can be enucleated if they are small; however, distal pancreatectomy carries little morbidity. Tumors of the head can usually be enucleated, so that pancreaticoduodenectomy can be avoided. In patients with malignant disease, metastases may respond to streptozocin, diazoxide, verapamil, or octreotide may successfully reduce insulin secretion and control symptoms. A diet of complex carbohydrates can also help stabilize serum glucose levels in the hyperinsulinemic patient.

Nonfunctional tumors are the most common pancreas lesions in MEN-1. Their management is specific to their size and risk of malignancy.

Pituitary Adenomas

Prolactin-secreting tumors occur most commonly in this setting, although Cushing disease or acromegaly develops in an occasional patient. Symptoms may result from compression of the optic chiasm, which produces bitemporal hemianopsia, or from prolactin excess, which produces amenorrhea and galactorrhea in female patients and hypogonadism in male patients.

Bromocriptine inhibits prolactin secretion and shrinks many prolactinomas. Refractory tumors and those producing other hormones can be managed by pituitary ablation or radiation.

Other Tumors

MEN-1 is associated much less frequently with adrenocortical tumors and benign thyroid adenomas. Lipomas and carcinoid tumors may also occur.

Clinical Features and Management of Multiple Endocrine Neoplasia Type 2

Like MEN-1, the MEN-2 syndromes are inherited in an autosomal dominant fashion with complete penetrance but variable phenotype. Bilateral MTC occurs in every affected patient. More frequently than the other syndromes, MEN-2B can arise as a new mutation that can be transmitted to subsequent generations.

Figure 76-19. Medullary thyroid carcinoma. Coronal section of a total thyroid resection shows bilateral involvement by a firm, pale tumor.

Medullary Thyroid Carcinoma

Medullary thyroid carcinoma accounts for about 10% of all thyroid malignancies, and 20% of cases occur in the familial setting of MEN-2A, MEN-2B, or familial non-MEN MTC. It is usually the first tumor that develops in these patients and typically appears in the second or third decade. Tumors are virtually always bilateral and develop in multiple areas of the middle and upper portions of the thyroid lobe (Fig. 76-19). Occasionally, in young people, a diffuse proliferation of parafollicular C cells, termed *C-cell hyperplasia*, is present without frankly invasive carcinoma. This finding is highly suggestive of one of the familial MTC syndromes. Patients typically present with a neck mass and may have hoarseness, dysphagia, or palpable cervical adenopathy. MTC may produce a variety of hormones, including calcitonin, adrenocorticotrophic hormone, prostaglandin, and serotonin. The hypercalcitoninemia is often asymptomatic, although severe diarrhea can develop.

By detecting minimal elevations of plasma calcitonin, it is possible to diagnose MTC at a clinically occult stage. Basal plasma calcitonin levels in normal subjects are in the range of 30 to 100 pg/mL. An increase to levels of 150 to 200 pg/mL occurs, however, after the administration of the potent secretagogues calcium and pentagastrin. The plasma calcitonin levels of patients with MTC show striking increases ($>1,000$ pg/mL) after provocative testing, so that they can be identified readily. Patients with occult disease may have only minimally elevated basal calcitonin levels that increase in response to secretagogues. The combined infusion of calcium and pentagastrin was the most effective screening test for familial MTC before genetic testing became available. By means of provocative testing in kindred members at risk for disease, MTC was diagnosed at a preclinical stage, and a greater percentage of these patients were cured by surgical therapy. With genetic testing now available, prophylactic thyroidectomy to prevent the development of MTC is possible for all affected people.

Postoperatively, the presence of residual MTC can be readily detected by provocative testing. Meticulous reoperation in patients with recurrent or persistently elevated plasma calcitonin levels postoperatively, including mediastinal dissection on occasion, can normalize elevated plasma calcitonin levels and apparently cure many of them.⁶³ For the patient with unresectable metastases, few therapeutic options are available. Neither radiation nor chemotherapy is of significant benefit.

The clinical course of patients with the MEN-2 syndromes is determined primarily by the status of their MTC. In the setting of MEN-2A, the tumors are often indolent and survival prolonged, even in the

presence of metastatic disease. By contrast, the tumors in patients with MEN-2B occur at an earlier age and are generally more aggressive neoplasms. Patients may succumb to the disease at a young age. As a consequence of this aggressiveness, the size of kindreds with the disease is typically small, and usually only a few generations are affected.

Pheochromocytoma

Pheochromocytomas are usually detected during the initial screening or follow-up of patients in whom MTC has already been diagnosed. They typically appear in the second or third decade of life, and about 80% are bilateral. Usually, pheochromocytomas are benign but multicentric, and they almost always arise in the adrenal medulla. In patients with MEN-2A or MEN-2B, hyperplasia of the adrenal medulla may develop first, grossly characterized by thickening of the medullary tissue in both adrenal glands.

Pheochromocytomas can be asymptomatic, but most commonly, patients have pounding frontal headaches, episodic diaphoresis, palpitations, or anxiety. Hypertension also occurs and is often episodic.

The diagnosis is made by measuring the plasma concentration of metanephrines. Patients with MEN-2A or MEN-2B and MTC should be evaluated for pheochromocytoma before they undergo thyroidectomy. If a patient is found to have both lesions, adrenalectomy should be performed first, followed by neck exploration. The abdomen is explored through a bilateral subcostal incision or, more typically, with a laparoscope.⁶⁴ Bilateral pheochromocytomas are treated by bilateral adrenalectomy. In patients with MEN-2A or MEN-2B and a unilateral pheochromocytoma, only the diseased adrenal gland is removed. In about 30% of patients treated in this manner, a tumor eventually develops in the opposite gland. In the remaining patients, this approach avoids the need for glucocorticoid and mineralocorticoid replacement and the risk for Addisonian crisis. After unilateral adrenalectomy, patients are carefully screened at 6-month or 1-year intervals with plasma metanephrine measurements.

Parathyroid Disease

Hyperparathyroidism develops in about one-third of patients with MEN-2A, although it is usually asymptomatic. Occasionally, nephrolithiasis develops. Bone disease is unusual. Frequently, enlarged parathyroid glands are found at operation for MTC, although the patient is still normocalcemic. Multiglandular chief cell hyperplasia is the predominant histologic finding in MEN-2A. Significant parathyroid disease rarely develops in MEN-2B.

Total parathyroidectomy and heterotopic autotransplantation are performed in hypercalcemic patients with MEN-2A. In normocalcemic patients with MEN-2A undergoing thyroidectomy for MTC, total parathyroidectomy and heterotopic autotransplantation are performed in one session to ensure that the complete thyroidectomy does not compromise the parathyroid blood supply and to avoid reoperation in the neck for subsequent hyperparathyroidism. Evidence suggests that these patients are more easily treated, with a lower incidence of recurrent hyperparathyroidism, than patients with MEN-1.

Nonendocrine Manifestations of Multiple

Endocrine Neoplasia Type 2B. In addition to MTC and pheochromocytoma, marked abnormalities of the nervous and musculoskeletal systems develop in patients with MEN-2B. The classic phenotype is characterized by thick lips and a thin, marfanoid habitus (Fig. 76-20A,B). The incidence of associated skeletal abnormalities is high; these include kyphosis, pectus excavatum, pes planus or cavus, and congenital dislocation of the hip. Diffuse autonomic nervous hypertrophy is another feature. Mucosal neuromas appear on the tongue (Fig. 76-20C), eyelids, lips, and pharynx. Slit-lamp examination may reveal hypertrophied corneal nerves. Ganglioneuromatosis develops in the submucosal and myenteric plexuses of the gastrointestinal tract. Constipation is common, and radiographic findings may suggest megacolon or Hirschsprung disease.

Figure 76-20. A,B: Characteristic appearance of patients with multiple endocrine neoplasia type IIB, including thick lips. C: Multiple mucosal neuromas on the tongue of a patient with MEN-2B. (From Norton JA, Froome LC, Farrell FE, et al. Multiple endocrine neoplasia type 2b: the most aggressive form of medullary thyroid carcinoma. *Surg Clin North Am* 1979;59:109.)

Chapter 77

Adrenal Gland

John A. Olson, Jr. and Douglas J. Turner

Key Points

- 1 Adrenocortical steroid hormones, glucocorticoids, mineralocorticoids, and androgenic steroids are all synthetic derivatives of cholesterol that are either extracted from plasma or synthesized intracellularly.
 - 2 Catecholamines of the adrenal medulla include epinephrine, norepinephrine, and dopamine, the vasoactive synthetic derivatives of the amino acid tyrosine.
 - 3 Cushing syndrome is adrenocorticotrophic hormone (ACTH) dependent in 80% to 90% of cases, most often because of an ACTH-secreting pituitary adenoma, though ectopic ACTH-producing nonendocrine tumors (mostly non–small-cell lung cancer and bronchial carcinoids) represent 10% to 20% of cases of ACTH-dependent Cushing syndrome; the remainder have a primary adrenal cause of hypercortisolism.
 - 4 An aldosterone-producing adrenal adenoma (Conn syndrome) is the source of primary hyperaldosteronism in 60% to 70% of cases while idiopathic bilateral adrenal hyperplasia causes most of the remaining cases of primary hyperaldosteronism; adrenocortical carcinoma is a rare cause of primary hyperaldosteronism.
 - 5 Surgical removal by laparoscopic adrenalectomy of an aldosterone-secreting adenoma results in durable improvement of hypertension and hypokalemia in 70% to 90% of patients; management of idiopathic adrenal hyperplasia is medical, because fewer than 20% to 30% of patients with this disease are cured by adrenalectomy.
 - 6 The congenital adrenal hyperplasias are autosomal recessive conditions resulting from inherited defects of one or several of the enzymes necessary for cortisol biosynthesis leading to ACTH overproduction and secondary hyperplasia of the adrenal cortex with shunting of cortisol precursors into adrenal androgen pathways; peripheral conversion of the excess adrenal androgens to testosterone causes virilization of the patient.
 - 7 Adrenocortical carcinoma has an estimated incidence of 0.5 to 2 cases per million per year, is very aggressive (most patients present with locoregionally advanced or distant disease), and hormone overproduction syndromes are frequent including hypercortisolism, hyperaldosteronism, or virilization.
 - 8 The *rule of tens* is a useful way to characterize pheochromocytoma: tumors are bilateral in 10% of cases, extraadrenal in 10%, familial in 10%, multicentric in 10%, and malignant in 10% and occur in children in 10% of cases; determination of plasma-fractionated metanephrines is the best test for diagnosis of pheochromocytoma.
 - 9 Unsuspected adrenal masses are detected by computed tomography in between 0.6% and 1.9% of healthy patients; the goal of evaluation is to distinguish and remove those adrenal masses that are functioning or likely to be malignant versus those that are neither and can be observed.
-

ANATOMY

The adrenal glands are bilateral, retroperitoneal, endocrine organs located adjacent to the superior pole of each kidney. These glands appear grossly as flat, triangular structures each weighing approximately 4 g. Each adrenal gland is composed of two distinct endocrine organs, the cortex and medulla. The outer adrenal cortex is bright yellow and nodular, whereas the adrenal medulla is red-brown in color and is sandwiched between the thin layers of the cortex. The adrenals are embedded in retroperitoneal perinephric fat but can be identified as distinct structures by their golden brown, nodular appearance. The right adrenal gland abuts the inferior vena cava medially and lies in close proximity to the

diaphragmatic crus posteriorly and the liver anteriorly. The left adrenal gland resides between the kidney and aorta, immediately deep to the tail of the pancreas and spleen.

Embryologically, fetal and definitive adrenal cortices arise from coelomic mesoderm near the urogenital ridge during the fourth to sixth weeks of gestation. Postnatally, the fetal cortex involutes, leaving only the definitive cortex to differentiate into the three adult zonae, the glomerulosa, fasciculata, and reticularis. The adrenal medulla develops from the neural crest during the fifth gestational week and migrates along paraaortic and paravertebral routes to join the developing cortex. Ectopic adrenal cortex and medulla may be found anywhere along their respective paths of embryologic migration. Most neural crest tissue regresses, however, extraadrenal neural crest derivatives may be found along the retroperitoneum and at the aortic bifurcation (organ of Zuckerkandl).

The adrenal cortex is composed of three distinct zones. The outer zona glomerulosa, located just beneath the fibrous gland capsule, is the site of mineralocorticoid production. The middle zona fasciculata, composed of linear arrays of large, foamy cells with lipid inclusions, is the predominant site of glucocorticoid and adrenal sex steroid biosynthesis. The inner zona reticularis is the primary location of synthesis of adrenal androgens. Both the zona fasciculata and zona reticularis respond to stimulation by adrenocorticotrophic hormone (ACTH). The adrenal medulla is smaller than the cortex. Cells of the adrenal medulla appear as homogeneous sheets, with large, irregular, atypical-looking nuclei. The cytoplasm of these cells has numerous secretory granules containing catecholamines, neuron-specific enolase, and chromogranin. Catecholamines in these granules precipitate chromium salts, which is the basis for the term *chromaffin cells*.

Figure 77-1. A: Arterial (dark shaded) and venous (light shaded) anatomy of the adrenal glands. B: Schematic showing outer adrenal cortex (light shaded) and inner adrenal medulla (dark shaded).

The adrenal glands have an extensive vascular supply derived from branches of the inferior phrenic artery superiorly, the aorta medially, and the renal artery inferiorly. Venous return from the right adrenal gland empties directly into the inferior vena cava through a wide but short central vein. Venous drainage from the left adrenal gland empties into a smaller vein that shares a common trunk with the left phrenic vein. Together they join the left renal vein (Fig. 77-1).

BIOCHEMISTRY AND PHYSIOLOGY

Adrenal Cortex

1 Adrenocortical steroid hormones, glucocorticoids, mineralocorticoids, and androgenic steroids are all synthetic derivatives of cholesterol that are either extracted from plasma or synthesized intracellularly (Fig. 77-2). In mitochondria of cells in the adrenal cortex, cholesterol is converted by desmolase

(CYP11A1) to delta-5-pregnenolone, the common parent compound for all adrenal cortex steroids. Pregnenolone is then shunted to the three biosynthetic pathways, each compartmentalized within the adrenal according to synthetic capabilities within each zone. In the zonae fasciculata and reticularis, pregnenolone is either converted to progesterone by 3-beta-hydroxysteroid dehydrogenase or is oxidized at position 17 by 17-alpha hydroxylase (CYP17) to form 17-hydroxypregnenolone. In the zona fasciculata, progesterone is hydroxylated by CYP17 at position 17 to form 17-hydroxyprogesterone. Subsequently, 17-hydroxyprogesterone is sequentially hydroxylated at the 21 position by 21-beta hydroxylase (CYP21A2) and at position 11 by 11-beta hydroxylase (CYP11B1) to form cortisol. In the zona reticularis, the androgenic steroids dehydroepiandrosterone (DHEA) and androstenedione are made from 17-hydroxypregnenolone and 17-hydroxyprogesterone, respectively. Collectively, the glucocorticoid and androgenic steroids are known as *17-hydroxy corticosteroids and 17-hydroxy ketosteroids*. In the zona glomerulosa, progesterone is not hydroxylated at the 17 position owing to the lack of enzyme at this location. Instead aldosterone is made from progesterone by a sequential series of hydroxylation steps at position 21 by CYP21A2, position 11 by CYP11B1, and position 18 by aldosterone synthase (CYP11B2 and P450c11as). The zona glomerulosa is well suited to aldosterone biosynthesis because of the relative lack of 17-hydroxylase and the exclusive expression of aldosterone synthase, required for the conversion of corticosterone to aldosterone.

Figure 77-2. Steroid biosynthetic pathways in the adrenal cortex. Steroids and precursors are shown in square boxes. Enzymes are shown in stippled boxes. Enzyme gene symbol designations are: CYP11A1, desmolase; CYP17, 17 α -hydroxylase ($\pm$ 17,20 lyase*); 3 β -HSD, 3 β -hydroxysteroid dehydrogenase; CYP21A2, 21-hydroxylase; CYP11B1, 11 β -hydroxylase; CYP11B2, Aldosterone synthase. *Inset:* Basic steroid ring structure. The four basic carbon rings are designated A, B, C, and D. Individual carbons at sites of steroidegenic enzyme activity are designated numerically.

Cortisol

Cortisol is the predominant glucocorticoid in humans. Production and release of cortisol is tightly regulated by a complex feedback relationship between the hypothalamus, corticotrophs of the anterior pituitary, and cells of the adrenal cortex zonae fasciculata and reticularis. This endocrine system is called the *hypothalamic-pituitary-adrenal (HPA) axis*. Communication within the HPA axis is mediated by synthesis and secretion of corticotrophin-releasing hormone (CRH) by the hypothalamus and ACTH production by corticotrophs of the anterior pituitary (Fig. 77-3). ACTH is a cleavage product of a precursor polipeptide, proopiomelanocortin (POMC) that is built of 241-amino-acid residues within corticotroph cells of the anterior and intermediate lobes of the pituitary. Several derivatives of POMC are important biologically active substances, including ACTH. Under stimulation of hypothalamic CRH stimulus, POMC can be cleaved into ACTH and β -lipotropic hormone in the anterior lobe. ACTH acts

directly on the adrenal to regulate cortisol production by cells within the zonae fasciculata and reticularis. Feedback loops involving cortisol, hypothalamic CRH, and pituitary ACTH keep the concentration of cortisol in plasma within a narrow range of 10 to 15 $\mu\text{g/dL}$. Typical daily production of cortisol in humans ranges from 10 to 30 mg and can increase to as high as 300 mg per day under conditions of maximal stress.

In circulation, cortisol is protein bound to transcortin and albumin with a small percentage of free cortisol available to target tissues. The half-life of cortisol in circulation is 90 minutes. Cortisol is metabolized in the liver to the inactive metabolites dihydrocortisol and tetrahydrocortisol, which become conjugated to glucuronidate and excreted in the urine. These urinary metabolites, collectively known as *17-hydroxycorticosteroids*, as well as free cortisol, can be measured in the urine.

Cortisol binds to specific intracellular cytoplasmic receptors, causing translocation of activated receptor–ligand complexes to the nucleus. Biologic effects result from transcriptional activation of genes and may be grouped into intermediary metabolism, immunomodulation, and regulation of intravascular volume (Table 77-1). Important effects of cortisol on intermediary metabolism center on raising blood glucose directly and indirectly by providing substrate for gluconeogenesis by the liver. These effects include (a) stimulation of glucagon and inhibition of insulin-stimulated glucose uptake by cells; (b) decrease in peripheral protein synthesis and increase in proteolysis, thus delivering gluconeogenic amino acids to the liver; and (c) stimulation of peripheral lipolysis. In effect, cortisol acts anabolically in vital organs to preserve glucose supply and catabolically in peripheral tissues to mobilize gluconeogenic substrates. Cortisol also possesses profound anti-inflammatory and immunosuppressive activities. Impairment of cellular immunity is due to inhibition of interleukin production, impairment of monocyte and neutrophil chemotaxis despite raised leukocyte counts, and reduction of T-cell activation. Humoral immunity is inhibited by inhibition of T-cell stimulation of B cells and by direct inhibition of B-cell proliferation and activation. These immunomodulatory effects may also underlie the impairment of normal wound healing seen in states of cortisol excess. Cortisol also regulates intravascular volume through renal retention of sodium and maintains blood pressure through inotropic and chronotropic effects on the heart as well as by increasing peripheral vascular resistance. In bone, glucocorticoids promote osteopenia by inhibition of bone formation by osteoblasts.

Figure 77-3. Schematic of hypothalamic–pituitary–adrenal axis for cortisol. Regulatory feedback relationships are designated with arrows.

Table 77-1 Systemic Effects of Cortisol

Function	Normal Amounts	Excessive Amounts
Metabolic		
Protein	Proteolysis	Muscle wasting
Glucose	Gluconeogenesis	Hyperglycemia
Fat	Low-use peripheral lipolysis	Limb thinness
	Central lipogenesis	Truncal obesity
Gastrointestinal	Mucosal cells	Ulceration
	Prostaglandin	Pancreatitis
Cardiovascular	Chronotropic, inotropic	Hypertension
	Vascular resistance	
Renal	Sodium resorption	Hypertension
Bone	Osteoblastic development	Osteoporosis
Inflammatory and immune	Circulating cells	Infection
	Soluble mediators	
	Antigen processing	
Wound healing	Fibroblasts	Striae
	Epithelial cell	Dehiscence

Figure 77-4. Regulatory relationships of renin, the angiotensins, and their sites of production and enzymatic conversion.

Aldosterone

Aldosterone is the principle mineralocorticoid in humans. Aldosterone secretion by the cells of the adrenal zona glomerulosa is regulated by the renin–angiotensin system and by plasma potassium (Fig. 77-4). Aldosterone is also regulated to a lesser degree by ACTH and plasma sodium concentration. Juxtaglomerular myoepithelial cells lining afferent arterioles of the kidney sense renal blood flow and pressure, and they secrete renin in response to decreased perfusion. Renin enzymatically activates angiotensinogen to the inactive decapeptide precursor, angiotensin I. Angiotensin I is converted to angiotensin II by angiotensin-converting enzyme in the lung. Angiotensin II has three major effects: (a) arteriolar vasoconstriction; (b) renal sodium retention; and (c) increased aldosterone biosynthesis, each of which results in sodium retention and potassium excretion by the kidney. These effects work together to maintain arterial blood pressure as well as blood volume. Physiologic conditions that stimulate the

renin–angiotensin cascade and aldosterone release include dehydration, upright posture, and hemorrhage. Inhibitory factors include volume repletion. Postural changes in renin–angiotensin and aldosterone are mediated by the sympathetic nervous system.

Under normal circumstances, aldosterone secretion is controlled by total body sodium and potassium levels. Excess sodium intake suppresses renin activity and leading to decreased aldosterone levels and increased renal excretion of sodium. Conversely, sodium depletion stimulates the renin–angiotensin system and aldosterone production, which promotes sodium retention by the kidney. Increased potassium intake directly decreases renin release and aldosterone production; decreasing potassium intake increases renin release. Humans with normal sodium intake typically produce 100 to 150 mg of aldosterone per day.

In circulation, aldosterone is bound to albumin and transcortin with a small percentage of free aldosterone available to target tissues. The half-life of aldosterone in plasma is 15 minutes. Aldosterone is metabolized rapidly in the liver and conjugated to glucuronidate, which is excreted in the urine. In liver failure, metabolism of aldosterone is impaired leading to elevated levels and fluid retention.

Aldosterone is the major regulator of extracellular fluid volume and potassium homeostasis (Table 77-2). Aldosterone binds to high-affinity aldosterone receptors in target tissues, including cells of the distal convoluted tubule in the kidney (the major site of action), the salivary glands, and colonic mucosa (minor sites). Stimulation of these cells results in retention of sodium and excretion of potassium. Retention of sodium in the kidney leads to passive reabsorption of water and an increase in extracellular fluid volume. To balance aldosterone-mediated retention of positively charged sodium ions, the kidney epithelium releases intracellular potassium into the distal convoluted tubule for excretion in the urine. Hydrogen ion is also released causing acidification of the urine.

Table 77-2 Effects of Aldosterone Secretion

Tubular Action	Normal Amounts	Excessive Amounts
Increased resorption of sodium	Protects against low-volume states	Hypertension Positive sodium balance Hyporeninemia
Decreased resorption of potassium	Protects against hyperkalemia	Hypokalemia Metabolic alkalosis Hyperglycemia Nocturia, polyuria Muscle weakness

Adrenal Androgens

Adrenal C-19 androgenic steroids, include DHEA and delta-4-androstenedione, are synthesized in cells of the zona reticularis. These steroids promote secondary sexual characteristics in men and virilization in women. DHEA is the major adrenal androgen, while androstenedione is relatively minor. Both are relatively weak androgens and exert their effects on target tissue after local tissue conversion to testosterone. Unlike gonadal androgens, adrenal androgens are regulated by ACTH, not gonadotropins, and can therefore be inhibited by glucocorticoid administration.

Adrenal Medulla

2 Catecholamines of the adrenal medulla include epinephrine, norepinephrine, and dopamine. These vasoactive hormones are synthetic derivatives of the amino acid tyrosine (Fig. 77-5). The biosynthetic pathway that converts tyrosine to active catecholamines involves four sequential enzymatic reactions: (a) tyrosine is converted to L-dihydroxyphenylalanine (dopa) by tyrosine hydroxylase; (b) dopa is converted to dopamine by aromatic-L-amino acid decarboxylase; (c) dopamine is converted to norepinephrine by dopamine beta hydroxylase; and (d) norepinephrine is converted to epinephrine by phenylethanolamine-N-methyltransferase (PNMT). Epinephrine is the major (80%) catecholamine stored in the adrenal medulla, followed by norepinephrine (20%) and dopamine (<1%). Tissue expression of the enzyme PNMT is limited to cells of either the adrenal medulla or organ of Zuckerkandl, located near the aortic bifurcation, thus most extraadrenal pheochromocytomas produce norepinephrine, rather than epinephrine.

Figure 77-5. Catecholamine biosynthetic and metabolic pathways. Precursors, catecholamines, and metabolites are shown in *square boxes*. Enzymes are shown in *stippled boxes*. Enzyme gene symbol designations are: TH, tyrosine hydroxylase; AADC, aromatic-L-amino acid decarboxylase; DBH, dopamine- β -hydroxylase; PNMT, phenylethanolamine-N-methyltransferase; COMT, catechol-O-methyl-transferase; MAO, monoamine oxidase. VMA, 3-methoxy-4-hydroxy-mandelic acid.

A complex regulatory network governs synthesis and secretion of catecholamines. Factors that increase catecholamine release include splanchnic nerve stimulation, stress, and glucocorticoids. The metabolic milieu within the adrenal medulla also greatly influences catecholamine synthesis by regulating enzymatic activity: glucocorticoids, phospholipids, cyclic adenosine monophosphate, adenosine triphosphate, protein kinase, and magnesium increase activity of PNMT and decrease catecholamine negative feedback. Catecholamines are stored and secreted from granules within cells of the medulla in association with the matrix protein chromogranin. Chromogranin A is measurable in the blood and their measurement may support the biochemical testing for pheochromocytoma, as well as other functional neuroendocrine tumors.

Catecholamines act on target tissues through membrane-bound receptors. Pharmacologic distinction of adrenergic receptors is made based on their relative responsiveness to natural and artificial bioamines. Alpha-adrenergic receptors show highest affinity for norepinephrine, less for epinephrine, and least for isoproterenol. Beta-adrenergic receptors are most responsive to isoproterenol and least to norepinephrine. In addition, specific antagonists recognize each receptor class: alpha-receptors are antagonized by phentolamine and phenoxybenzamine, and beta-receptors are blocked by propranolol and related compounds. Beta-adrenergic receptor subtypes include beta-1, which is present in cardiac muscle, adipose tissue, and small intestine, and beta-2 receptors, which are found in vascular, tracheal, and uterine smooth muscle, skeletal muscle, and liver. Alpha-adrenergic receptors are similarly subdivided: alpha-1 receptors mediate vasoconstriction whereas alpha-2 receptors modulate presynaptic norepinephrine release and platelet aggregation (Table 77-3).

Metabolism of catecholamines occurs through three mechanisms: by specific uptake by sympathetic neurons, by nonspecific uptake and degradation by peripheral tissues, and by excretion in the urine. Catecholamines are metabolized in liver and kidney by two enzymes, monoamine oxidase and catechol-O-methyltransferase (Fig. 77-5). In these tissues, monoamine oxidase and catechol-O-methyltransferase convert epinephrine or norepinephrine to normetanephrine, and metanephrine, 3,4-dihydroxy-mandelic acid, and 3-methoxy-4-hydroxy-mandelic acid. These inactive metabolites are excreted by the kidney and are measurable in the urine either as free compounds or as conjugates of glucuronide or sulfate.

DISEASES OF THE ADRENAL CORTEX

Hypercortisolism

The term *hypercortisolism* refers to the physiologic state of glucocorticoid excess. This disorder is rare, with an estimated incidence of 10 per million population. The most common cause of hypercortisolism is the administration of exogenous steroids as immunosuppressive therapy for inflammatory disorders or after organ transplantation. Endogenous hypercortisolism, or Cushing syndrome, in all cases is caused by increased adrenal production of cortisol, which may be ACTH dependent (ACTH elevated) or independent (ACTH suppressed). Some patients with major depression or chronic alcoholism have abnormally high cortisol secretion and may appear to have clinical and biochemical features of Cushing syndrome. Pseudo-Cushing syndrome responds to treatment of the underlying disorder.

3 Cushing syndrome is ACTH dependent in 80% to 90% of cases. Such ACTH-dependent hypercortisolism is most often (80% to 90% of cases) caused by an ACTH-secreting pituitary adenoma (termed *Cushing disease*). Ectopic ACTH-producing nonendocrine tumors (mostly non-small-cell lung cancer and bronchial carcinoids) represent 10% to 20% of cases of ACTH-dependent Cushing syndrome. All causes of ACTH-dependent Cushing syndrome involve bilateral adrenal hyperplasia in response to ACTH stimulation.

Of patients with endogenous Cushing syndrome, 10% to 25% have ACTH-independent disease caused by a primary adrenal cause. A solitary adrenal adenoma is present in 80% to 90% of these patients and is often associated with atrophy of both adjacent and contralateral adrenocortical tissue. Nodular cortical hyperplasia of both glands causes the remaining cases of primary adrenal Cushing syndrome. Although nodular hyperplasia represents a diffuse process, one or more distinct nodules may simulate adenomas. Rarely tumors secrete CRH ectopically, leading to ACTH-independent (though ACTH is elevated) Cushing syndrome with secondary adrenal hypertrophy.

Signs and Symptoms

Clinical features of cortisol excess are listed in [Table 77-1](#). Truncal obesity (*orange on toothpicks*), accumulation of fat around the head and neck (*moon facies* and *buffalo hump*), and muscle wasting are present in most patients. Patients often have purple striae and purpura on the abdomen and extremities. Hirsutism may be present in women. High blood pressure is common and is usually moderate, although malignant hypertension has been observed. Bone pain and muscle weakness (caused by proximal muscle wasting and hypokalemia) are also common. Osteoporosis is common and pathologic fractures are observed in advanced cases. Neurologic symptoms, including headache, emotional lability, depression, and even psychosis may be observed. Glucose intolerance is common but can often be managed by alterations in diet alone. The serum potassium level may be low secondary to the weak mineralocorticoid properties of cortisol. Autonomous glucocorticoid production without specific signs and symptoms of Cushing syndrome is termed subclinical Cushing syndrome. This condition is being diagnosed with increased frequency because of the detection of adrenal incidentalomas by routine CT. A substantial percentage of incidentalomas are hormonally active, with 5% to 20% of the tumors producing glucocorticoids. The estimated prevalence of subclinical hypercortisolism is 79 cases per 100,000 persons, substantially higher than classic Cushing syndrome. Depending on the amounts of

glucocorticoids secreted by the tumor, the clinical spectrum ranges from slightly attenuated diurnal cortisol rhythm to atrophy of the contralateral adrenal gland. Patients with subclinical Cushing syndrome lack the classical stigmata of hypercortisolism but have a high prevalence of obesity, hypertension, and type 2 diabetes.

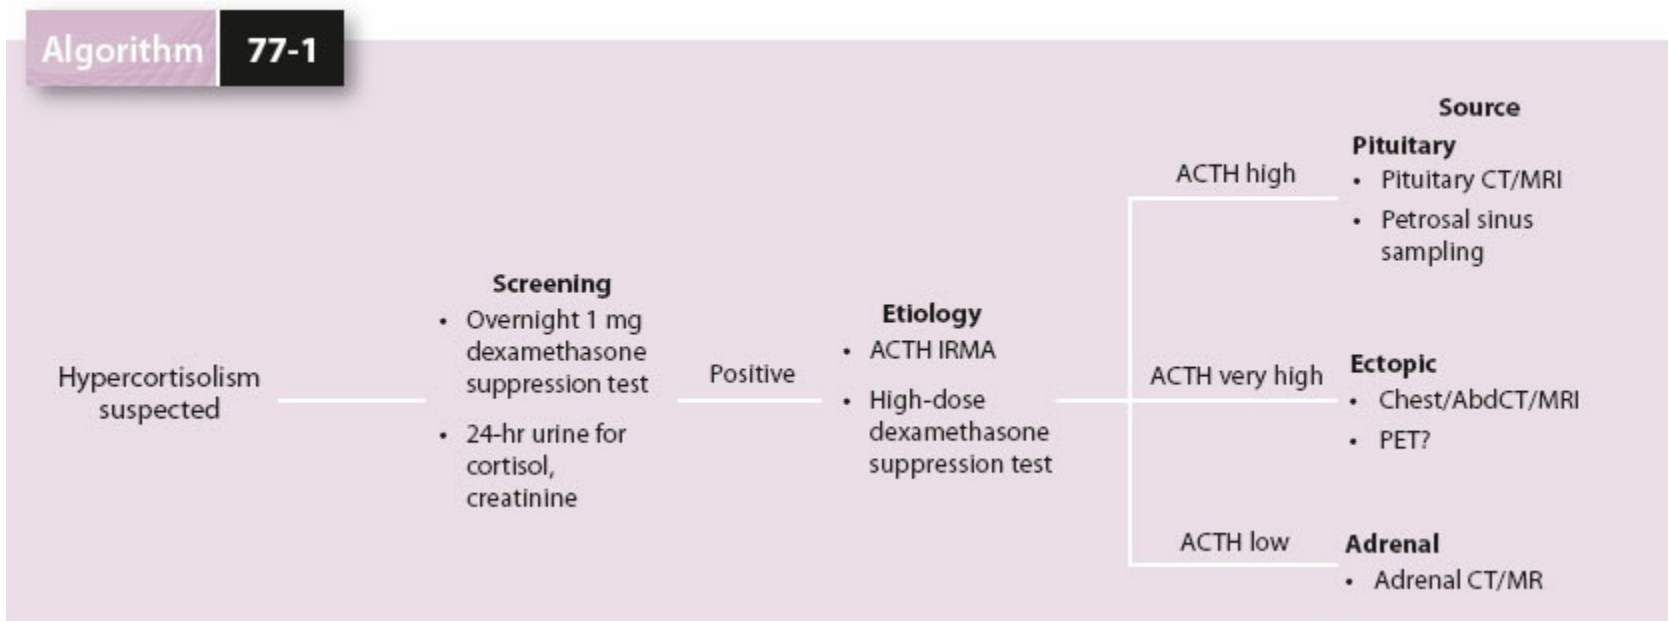

Diagnosis

The investigation of suspected Cushing syndrome should answer two questions: (a) Does the patient have hypercortisolism? (b) If the answer is yes, then what is the cause? It is worthwhile to emphasize that the diagnosis of Cushing syndrome is biochemical. Radiologic investigations should not be undertaken until Cushing syndrome has been confirmed and its likely etiology characterized biochemically.

Hypercortisolism insensitive to suppression by administration of exogenous glucocorticoid is the *sine qua non* of Cushing syndrome. The low-dose dexamethasone suppression test is the best test in patients with suspected Cushing syndrome. For this test, 1 mg of dexamethasone is administered orally at 11 PM and plasma cortisol is obtained at 8 AM the following day. Normal individuals suppress cortisol to below 5 µg/dL. Patients with Cushing syndrome fail to suppress below 5 µg/dL. False-positive test results occur in 10% to 15% of cases with the overnight test and occur especially in patients with obesity or alcoholism or in those taking estrogens or phenytoin. Measurement of free cortisol (not metabolites) in three consecutive 24-hour collections of urine is also a good screening test for Cushing syndrome. Collections should include concurrent creatinine measurement to evaluate the completeness of the collection. A 24-hour urinary-free cortisol level greater than 100 µg is diagnostic of Cushing syndrome. This test may be less sensitive than the low-dose dexamethasone suppression test in mild hypercortisolism. Plasma cortisol levels can normally vary considerably during a 24-hour period, so a single random plasma cortisol level is not helpful in establishing a diagnosis of Cushing syndrome.

Once the presence of hypercortisolism is established, the next task is to determine ACTH-dependent (pituitary or ectopic source) from ACTH-independent (primary adrenal) causes. Measurement of basal ACTH by immunoradiometric assay is the best test to make this distinction. Plasma ACTH levels are normally between 10 and 100 pg. Suppression of the absolute level of ACTH below 5 pg/mL is nearly diagnostic of adrenocortical neoplasms, which secrete high levels of cortisol and inhibit ACTH release by the pituitary. Patients with pituitary neoplasms and secondary bilateral adrenocortical hyperplasia have ACTH levels that may range from the upper limits of normal (15 pg/mL) to 500 pg/mL. The highest plasma levels of ACTH (more than 1,000 pg/mL) are in patients with ACTH-producing nonendocrine tumors, such as non-small-cell lung cancer.

Although 80% to 90% of patients with ACTH-dependent Cushing syndrome have Cushing disease, a high dose dexamethasone suppression test may be required to exclude ectopic ACTH syndrome. Hypercortisolism caused by ACTH-secreting pituitary adenomas is suppressed at least partially by high dexamethasone, whereas hypercortisolism caused by adrenal tumors and ectopic ACTH-producing tumors is not suppressed. For this test 2 mg dexamethasone is administered orally every 6 hours for 2 days, and a 24-hour urine collection for free cortisol is taken during the second day. About 90% of patients with pituitary source Cushing disease have a 50% reduction in urine-free cortisol. The specificity of the test can be improved to 100% for diagnosing pituitary disease if more than 90% suppression in urinary-free cortisol is used.

Algorithm 77-1. Diagnosis of hypercortisolism. ACTH, adrenocorticotrophic hormone; IRMA, immunoradiometric assay; CT,

Biochemical testing of suspected Cushing syndrome is followed by radiologic studies. Pituitary adenomas are best imaged with gadolinium-enhanced magnetic resonance imaging (MRI) of the sella turcica, which has a sensitivity approaching 100%, although small pituitary microadenomas may be missed. Patients with ACTH-independent Cushing syndrome require thin-section CT or MRI of the adrenal, which identifies adrenal abnormalities with more than 95% sensitivity. CT or MRI of the chest may identify a source of ectopic ACTH and should be undertaken in patients with elevated ACTH and hypercortisolism that cannot be suppressed by high-dose dexamethasone.

Despite the accuracy of biochemical testing and radiographic localization, a pituitary versus ectopic source of ACTH sometimes cannot be determined. Bilateral inferior petrosal sinus sampling is the best test to settle this issue. Simultaneous bilateral petrosal sinus and peripheral blood samples are obtained before and after peripheral intravenous injection of 1 µg/kg CRH. An inferior petrosal sinus to peripheral plasma ACTH ratio of 2.0 at basal stimulated or of 3.0 after CRH administration is 100% sensitive and specific for pituitary adenoma. Comparison of right and left inferior petrosal sinus ratios may also lateralize the adenoma.

The laboratory approach to the diagnosis of Cushing syndrome is summarized in [Algorithm 77-1](#). A careful history and physical examination form the basis for suspecting this condition. A low-dose dexamethasone suppression test and/or urinary-free cortisol measurement provide initial evidence for the diagnosis. Plasma ACTH determination and the high-dose dexamethasone suppression test are then used to identify the underlying cause of excess cortisol production by the adrenal cortex. Imaging studies support the cause of Cushing syndrome suggested by biochemical testing and localize the site for subsequent treatment.

Treatment

ACTH-dependent Cushing syndrome is best treated by removing the source of ACTH excess. In the case of Cushing disease, transsphenoidal resection of the pituitary microadenoma is successful in 80% or more of cases. If a microadenoma is not found, then hemihypophysectomy may be performed with the understanding that fertility may be impaired. Pituitary irradiation is a good treatment option when fertility is desired, when a tumor is not found or is unresectable, or cure is not achieved by transsphenoidal resection of a tumor. Debulking of unresectable primary lesions or recurrences with or without bilateral adrenalectomy may provide palliation in some patients. Treatment of ectopic ACTH syndrome involves removal of the primary lesion. Medical adrenalectomy with metyrapone, aminoglutethimide, and mitotane has been used to suppress production of corticosteroid in inoperable cases for both pituitary and ectopic sources of ACTH. Bilateral adrenalectomy is a good option for patients intolerant of mitotane.

ACTH-independent Cushing syndrome is best treated by removal of the adrenal tumor and affected gland. Small lesions, less than 6 cm in diameter, may be resected laparoscopically. Lesions larger than 6 cm or those suspected of being carcinoma require an anterior open approach. Resection of cortisol-producing benign adrenal adenomas is curative and prognosis is good following resection. Cortisol-producing adrenocortical carcinomas recur frequently following adrenalectomy, heralded by the reemergence of hypercortisolism. Micronodular pigmented hyperplasia and macronodular adrenal hyperplasia may involve both adrenal glands. These conditions are cured only by bilateral adrenalectomy. Medical adrenalectomy with mitotane or agents interfering with cortisol production is not currently recommended.

Whether patients with subclinical Cushing syndrome should undergo adrenalectomy is unclear. Several small series have demonstrated weight loss, an improvement in hypertension and glucose control following adrenalectomy for subclinical Cushing syndrome. Furthermore, patients with subclinical Cushing syndrome may progress to overt Cushing syndrome as frequently as 12.5% at 1 year. Accordingly, adrenalectomy for subclinical Cushing syndrome may be beneficial and is reasonable in young patients, patients with suppressed plasma ACTH, and patients with a recent weight gain, substantial obesity, arterial hypertension, diabetes mellitus, and osteopenia. Truly asymptomatic patients with normal plasma ACTH concentrations and the elderly or unfit may be observed. Demonstration of the benefits of surgery versus conservative treatment in patients with subclinical Cushing syndrome will require a randomized prospective trial.

All patients who undergo adrenalectomy for Cushing syndrome require perioperative and postoperative glucocorticoid replacement, since the contralateral gland is suppressed. Replacement

therapy with hydrocortisone, 12 mg/m² per day, may be required as long as 2 years postoperatively. Adequacy of replacement is monitored clinically. The duration of replacement therapy is guided by normalization of the ACTH stimulation test.

Hyperaldosteronism

Hyperaldosteronism is a syndrome of hypertension and hypokalemia caused by autonomous adrenal secretion of the mineralocorticoid aldosterone. Hyperaldosteronism may be primary, as a result of an adrenal neoplasm with suppressed plasma renin, or may be secondary, as a result of elevated plasma renin. Primary hyperaldosteronism is twice as common in women as in men, and it usually occurs between the ages of 30 and 50 years. Screening of hypertensive patients with plasma aldosterone and plasma renin activity (PRA) has suggested that primary hyperaldosteronism may be the underlying cause of up to 15% of cases of essential hypertension.

Algorithm 77-2. Diagnosis and management of hyperaldosteronism. PRA, plasma renin activity; PAC, plasma aldosterone concentration; CT, computed tomography; AVS, bilateral adrenal venous sampling.

4 An aldosterone-producing adrenal adenoma (Conn syndrome) is the source of primary hyperaldosteronism in 60% to 70% of cases. Idiopathic bilateral adrenal hyperplasia causes the remaining cases of primary hyperaldosteronism. Adrenocortical carcinoma is a rare cause of primary hyperaldosteronism. Autosomal dominant glucocorticoid-suppressible hyperaldosteronism is a rare cause of hyperaldosteronism resulting from the fusion of the ACTH-responsive 11-beta hydroxylase gene promoter to the aldosterone synthase gene in cells of the adrenal cortex.

Secondary hyperaldosteronism is a physiologic response of the renin–angiotensin system to decreased renal perfusion due to renal artery stenosis, cirrhosis, congestive heart failure, and normal pregnancy. The adrenal cortex functions normally and secretes aldosterone in response to the elevated plasma renin and angiotensin caused by these conditions. Secondary hyperaldosteronism responds to treatment of the underlying cause.

Signs and Symptoms

Clinical manifestations of primary hyperaldosteronism are attributable to hypersecretion of aldosterone by the adrenal gland (Table 77-2). Aldosterone-mediated retention of sodium and excretion of potassium and hydrogen ion by the kidney causes moderate diastolic hypertension. Edema is absent. Hypokalemia occurs spontaneously in 80% to 90% of patients with primary hyperaldosteronism but may be normal. Hypokalemia is easily provokable in the remaining patients. Potassium depletion frequently causes symptoms of muscle weakness and fatigue, polyuria and polydipsia, as well as impaired insulin secretion and fasting hyperglycemia. Primary hyperaldosteronism should be suspected in hypertensive patients with spontaneous hypokalemia (serum concentration <3.5 mEq/L), moderate hypokalemia (serum potassium concentration <3.0) during diuretic therapy despite concomitant use of oral potassium or potassium-sparing diuretics, or refractory hypertension without explanation.

Diagnosis

The clinical hallmarks of primary hyperaldosteronism are (a) diastolic hypertension without edema; (b) suppression of plasma renin in the face of volume depletion; and (c) hypersecretion of aldosterone that fails to suppress with intravascular volume expansion. Diagnostic evaluation must establish primary hyperaldosteronism, discern surgically correctable adrenal adenoma from medically treatable idiopathic hyperplasia, and localize an adrenal tumor ([Algorithm 77-2](#)).

Demonstration of an elevated plasma aldosterone concentration (PAC) in the setting of suppressed PRA is the best test to establish primary hyperaldosteronism. The ratio in normal subjects and patients with essential hypertension is 4:10 compared with more than 30 in most patients with primary hyperaldosteronism. A PAC of greater than 20 ng/dL and a PAC/PRA ratio of greater than 30 are diagnostic for aldosteronoma with almost 90% sensitivity. A serum potassium value less than 3.5 mEq/L and urinary potassium excretion greater than 30 mEq/day also support a diagnosis of primary hyperaldosteronism. Before biochemical evaluation, patients need to be potassium repleted and have an adequate sodium intake. Medications including ACE inhibitors and spironolactone should be withheld for at least 4 weeks before study.

An elevated PAC/PRA ratio alone does not establish the diagnosis of primary hyperaldosteronism, which must be confirmed by demonstrating inappropriate aldosterone secretion with salt loading. This involves a 24-hour urine collection for sodium and aldosterone after 3 days of a high-sodium diet. The 24-hour urinary excretion of aldosterone should be greater than 14 μ g per 24 hours after a high-salt diet for patients with primary hyperaldosteronism. An intravenous saline infusion test or captopril challenge test is also a reliable method to confirm primary hyperaldosteronism. These tests are not usually required.

After the diagnosis of primary hyperaldosteronism is made, distinction must be made between an aldosteronoma and idiopathic adrenal hyperplasia. The first test measures aldosterone in blood collected at 8 AM from a patient who has been supine overnight. Laboratory studies are repeated 4 hours later after the patient has been upright. Aldosterone secretion in patients with an aldosteronoma is unaffected by postural changes (<20 ng/dL), whereas, in patients with idiopathic adrenal hyperplasia, plasma aldosterone levels are elevated 33% (>20 ng/dL) or more by postural changes.

Figure 77-6. Computed tomography scan of right adrenal aldosteronoma. *Short arrow* shows aldosteronoma. *Long arrow* shows normal contralateral adrenal gland.

High-resolution adrenal computed tomography (CT) is the best test for localization of an adrenal tumor ([Fig. 77-6](#)). CT will detect an aldosterone-producing adenoma in 90% of cases overall. The presence of a unilateral adenoma greater than 1 cm on CT and supportive biochemical evidence of an aldosteronoma are generally all that is needed to make the diagnosis in most patients under 40 years of age. MRI is less effective and more costly but may be useful during pregnancy or in situations in which intravenous contrast medium injection is undesirable. The test of 6-[beta](131-I)-iodo-methyl-19-norcholesterol (NP-59) scintigraphy identifies functional tumors and discriminates aldosteronoma from adrenal hyperplasia with an overall accuracy of approximately 75%, but requires a tumor of sufficient size (>1 cm) for imaging to be dependable.

Adrenal vein sampling to lateralize the source of aldosterone production is useful in patients with hyperaldosteronism when there is no adrenal abnormality on CT or MRI or when both adrenal glands are abnormal but asymmetric. Further, patients older than 40 years, in whom the possibility of a

nonfunctioning adenoma is statistically higher, may benefit from routine sampling. Percutaneous transfemoral cannulation of both adrenal veins is performed and intravenous ACTH (50 μ /hr) is administered. Simultaneous adrenal vein blood samples for aldosterone and cortisol are taken before and after ACTH injection, and their ratios are determined. The PAC is markedly higher (at least fourfold) on the side of an adenoma, whereas there is little or no left–right gradient present in cases of bilateral adrenal hyperplasia. A 10-fold gradient of cortisol in adrenal veins to a peripheral sample ensures adequacy adrenal vein cannulation. This study is greater than 90% accurate and has been shown to alter management in 30% to 50% of patients, even in those with an apparent unilateral adenoma. This test is technically difficult and may be unsuccessful in 25% of patients. Emerging data suggest that adrenal vein sampling may be superior to CT in differentiating the source of aldosterone production in patients with hyperaldosteronism.

Treatment

5 Surgical removal of an aldosterone-secreting adenoma (Fig. 77-7) results in durable improvement of hypertension and hypokalemia in 70% to 90% of patients. Laparoscopic adrenalectomy is the preferred approach to remove these tumors. Morbidity and mortality following these procedures are almost negligible. Preoperative spironolactone or eplerenone and potassium are given to replenish potassium stores and correct alkalosis before anesthesia. Preoperatively, a significant fall in blood pressure with aldosterone receptor antagonists predicts a successful outcome after adrenalectomy. Response to adrenalectomy is also influenced by the duration and severity of hypertension and by the presence of histologic changes in the kidney. Age greater than 50 years, male sex, and the presence of multiple nodules within the adrenal is also associated with a poor response to surgery.

Management of idiopathic adrenal hyperplasia is medical because fewer than 20% to 30% of patients with this disease are cured by adrenalectomy. Idiopathic adrenal hyperplasia is treated with spironolactone or with newer aldosterone antagonist eplerenone. Other potassium sparing diuretics may be used including triamterene and amiloride. Treatment of glucocorticoid-suppressible hyperaldosteronism includes dexamethasone 0.5 to 1.0 mg daily. Glucocorticoids are used in small doses to avoid Cushing syndrome.

Congenital Adrenal Hyperplasia

6 The congenital adrenal hyperplasias are autosomal recessive conditions resulting from inherited defects of one or several of the enzymes necessary for cortisol biosynthesis (Fig. 77-8). Cortisol deficiency leads to ACTH overproduction and secondary hyperplasia of the adrenal cortex with shunting of cortisol precursors into adrenal androgen pathways. Peripheral tissues convert the excess adrenal androgens to testosterone, which causes virilization of the patient.

Most cases (>90%) of congenital adrenal hyperplasia are secondary to deficiency of 21-hydroxylase (CYP21A2) resulting from mutation of the gene on the short arm of chromosome 6. Two forms of this deficiency are recognized; partial or complete. The complete form is characterized by androgen excess at birth, with virilization, hypovolemia, hyponatremia, hyperkalemia, and hyperpigmentation. The partial form is characterized by virilization only and may present in adolescence or adulthood.

Figure 77-7. Aldosteronoma within right adrenal gland shown in Figure 77-6.

Figure 77-8. Schematic representation of the mechanism underlying congenital adrenal hyperplasias. Enzymatic defects in the adrenal gland prevent normal production of cortisol with resulting loss of negative feedback to the hypothalamus and pituitary. Chronic adrenocorticotrophic hormone stimulation of the adrenal gland shunts steroid precursors through androgenic and mineralocorticoid pathways, leading to the overproduction of androgens and mineralocorticoids. The most common deficiencies are CYP21A2 (21-hydroxylase), CYP11B1 (11 β -hydroxylase), and 3- β -HSD (3- β -hydroxysteroid dehydrogenase).

Of the remaining causes of congenital adrenal hyperplasia, 11-beta-hydroxylase deficiency (CYP11B1) is the second-most common cause, followed by 3-beta-hydroxydehydrogenase and 17-hydroxylase (CYP17) deficiency. Congenital lipoid adrenal hyperplasia is the most severe form of congenital adrenal hyperplasia and is often fatal (Table 77-4).

Signs and Symptoms

Prenatal adrenal virilization in females produces ambiguous external genitalia (female pseudohermaphroditism). The ovaries, fallopian tubes, and uterus develop normally and patients are fertile. Postnatal congenital adrenal hyperplasia causes virilization of females and precocious puberty of males. Females develop hirsutism, polycystic ovaries, and irregular menses. Male patients exhibit secondary sexual characteristics by age 2 or 3 years. Fertility is often impaired. Both sexes experience rapid somatic growth and short stature. Virilization, salt wasting, and hyperpigmentation are variably present with the non-21-hydroxylase forms of congenital adrenal hyperplasias.

Diagnosis

Elevated plasma 17-hydroxyprogesterone is the most characteristic abnormality found in 21-hydroxylase deficiency. Both plasma cortisol and 24-hour free urinary cortisol excretion are variably reduced. Diagnosis of other forms of the disease involves demonstration of elevated levels of enzyme substrate: corticosterone and 11-deoxycortisol for 11-beta hydroxylase; dehydroepiandrosterone and 17-delta-5 hydroxypregnenolone for 3-beta hydroxydehydrogenase; and deoxycorticosterone and corticosterone for 17-beta-hydroxylase deficiency (Table 77-4).

Treatment

The treatment of 21-hydroxylase deficiency is glucocorticoid and mineralocorticoid replacement. Clinical management is often complicated by inadequately treated hyperandrogenism or iatrogenic hypercortisolism, or both. New treatment approaches under investigation include combination therapy to block androgen action and inhibit estrogen production, and bilateral adrenalectomy in the most severely affected patients. Female patients with ambiguous genitalia may require surgical correction as infants. Treatment of congenital adrenal hyperplasias caused by other enzyme deficiencies includes steroid and electrolyte replacement and surgical correction of the external genitalia in affected female infants.

Virilizing and Feminizing Adrenal Tumors

Excess production of adrenal androgens by an adrenal adenoma or carcinoma can produce virilizing features either alone or more commonly in addition to Cushing syndrome. Development of an adrenal virilizing tumor in women causes hirsutism and masculinization. Males with these tumors may present late with signs and symptoms of tumor enlargement or distant metastases develop. Virilizing tumors secrete androgen precursor, dehydroepiandrosterone, which can be measured either directly in plasma or in urine as a 17-ketosteroid. Feminizing adrenal neoplasms are extremely rare. Abdominal CT is subsequently used to localize the lesion. Resection of tumor and involved adrenal gland is the primary treatment for patients with adrenal virilizing tumors. Tumor recurrence is heralded by return of virilization or by detection of increased 17-ketosteroids in the urine. Tumor debulking or inhibition of steroidogenesis with aminoglutethimide or mitotane may be useful in controlling signs and symptoms in patients with metastatic disease.

7 Adrenocortical Carcinoma

Adrenocortical carcinoma is a rare malignancy with an estimated incidence of 0.5 to 2 cases per million per year. Presentation peaks in the first and fifth decades of life. The prevalence is higher in females than in males (1.4 to 2:1). The cause of adrenocortical carcinoma is unknown, although somatic mutations in P53 and inheritance of this tumor in patients with germline mutations in P53 (Li Fraumeni syndrome) implicate this tumor suppressor gene in its pathogenesis (1).

Signs and Symptoms

Adrenocortical carcinoma is a very aggressive malignancy, and most patients (up to 75%) present with locoregionally advanced or distant disease. Syndromes of adrenal hormone overproduction are frequent (up to 60%) and may include hypercortisolism, hyperaldosteronism, or virilization. Patients with rapidly progressive Cushing syndrome or mixed presentations with signs of both Cushing syndrome and virilization should be suspected of having adrenocortical carcinoma. Nonfunctioning adrenocortical carcinomas present most commonly as abdominal pain or mass with vague symptoms of nausea, weight loss, and fatigue.

Diagnosis

Patients with suspected adrenocortical carcinoma should have biochemical testing to identify hormone overproduction followed by staging investigations including cross-sectional imaging and bone scans. Contrast-enhanced CT of the abdomen and chest is important to preoperatively diagnose local tumor invasion and metastatic lesions as well as to confirm a functioning contralateral kidney (Fig. 77-9). In the absence of distant metastases or local invasion, preoperative distinction between large adenomas and carcinomas can be difficult, although large (>6 cm) adrenal masses that extend to nearby structures on CT scanning should be approached as carcinomas. Biopsy of adrenal lesions suspected of being adrenocortical carcinoma is unnecessary and should be avoided. The risk of seeding and the inability of histologic examination to distinguish between adenoma and carcinoma underlie this approach. Biopsy of extraadrenal lesions may be performed to confirm metastatic disease.

Table 77-4 Congenital Adrenal Hyperplasias

Disease	21-Hydroxylase Deficiency	11 β -Hydroxylase Deficiency	Aldosterone Synthase Deficiency	17 α -Hydroxylase Deficiency	3 β -hydroxysteroid Dehydrogenase Deficiency	Lipoid Hyperplasia
Defective gene	<i>CYP21</i>	<i>CYP11B1</i>	<i>CYP11B2</i>	<i>CYP17</i>	<i>HSD3B2</i>	<i>STAR</i>
Ambiguous genitalia	Females	Females	No	Males	Males	Males

Figure 77-9. Computed tomography scan of right adrenocortical carcinoma showing invasion of liver and inferior vena cava. Note that a contralateral kidney is present and functioning.

A definitive diagnosis of adrenocortical carcinoma requires pathologic demonstration of tumor invasion to adjacent organs or spread to lymph nodes or distant sites. Practically, any adrenal neoplasm larger than 6 cm or weighing more than 100 g should be considered malignant. Histologic features of tumor necrosis, hemorrhage, and local invasion are gross pathologic evidence of carcinoma, while cells with large, hyperchromatic nuclei and more than 20 mitoses per high-power field suggest malignancy.

Treatment

Surgical resection is the mainstay of treatment for all stages of adrenocortical carcinoma. Complete resection of locally confined tumor is the only chance for cure from adrenocortical carcinoma. However, distant or local spread is evident in 65% of cases at presentation and a minority of patients is resectable with curative intent. Recurrence rates after surgery range from 38 to 85%, depending on stage at presentation (Table 77-5).

Many patients with adrenocortical carcinoma present with metastatic disease, involving the lung, lymph nodes, liver, or bone. Resection or surgical debulking of locally advanced or metastatic lesions may provide symptomatic relief for select patients, especially those with low-grade, slow-growing, hormonally productive cancers. Symptomatic recurrent or metastatic disease is best treated by resection

when feasible.

Chemotherapy for adrenocortical carcinoma usually includes mitotane, although no controlled studies have established its efficacy in this disease. Partial responses to mitotane occur in less than a third of patients, and survival is unchanged. Adjuvant chemotherapy with mitotane after complete resection for adrenocortical carcinoma is unproven and toxic so that many oncologists reserve its use for recurrent, unresectable or metastatic disease. Cisplatin in combination with mitotane or doxorubicin and 5-fluoruracil have been applied in metastatic disease with partial responses noted.

STAGING

Table 77-5 American Joint Committee on Cancer Staging of Adrenocortical Carcinoma, with 5-Year Survival Rates

Stage	Criteria	
Tumor		
T1	Tumor <5 cm, no invasion	
T2	Tumor >5 cm, no invasion	
T3	Tumor with invasion to fat	
T4	Tumor with organ invasion	
Lymph nodes		
N0	No lymph node metastasis	
N1	Lymph node metastasis present	
Metastasis		
M0	No distant metastasis	
M1	Distant metastasis present	
Stage Group	TNM	5-Year Survival Rate
I	T1 (<5 cm), N0, M0	30–45%
II	T2 (>5 cm), N0, M0	12–57%
III	T1–2, N1, M0 T3, N0, M0	5–18%
IV	Any T, any N, M1 T3–4, N1, M0	0

The prognosis of adrenocortical carcinoma is poor. Median survival following diagnosis for all patients is approximately 18 months. Overall survival following resection for all stages of adrenocortical cancer is 15% to 47% at 5 years. Stage-specific 5-year survival is 30% to 45% for stage I, 12% to 57% for stage II, 5% to 18% for stage III, and 0 for stage IV disease.

DISEASES OF THE ADRENAL MEDULLA

Pheochromocytoma

8 Pheochromocytomas are functional adrenal tumors that arise from neuroectodermal cells of the adrenal medulla or in certain extraadrenal sites. These tumors are uncommon, occurring in 0.005% to 0.1% of persons, but occur with increased frequency in hypertensive populations (0.2% incidence) and in heritable endocrine tumor syndromes. The peak incidence of pheochromocytoma occurs during the fourth and fifth decades of life, and men and women are affected about equally. The *rule of tens* is a useful way to characterize pheochromocytoma: tumors are bilateral in 10% of cases, extraadrenal in 10%, familial in 10%, multicentric in 10%, and malignant in 10% and occur in children in 10% of cases.

Approximately 10% of pheochromocytomas are extraadrenal, although most (98%) are still located within the abdomen. Extraadrenal pheochromocytomas can occur at any site in the abdomen where chromaffin tissue is located and have been found in the paravertebral ganglia, the organ of Zuckerkandl, and the urinary bladder. Clues to the presence of extraadrenal pheochromocytoma are predominance of norepinephrine because extraadrenal sites lack the enzyme necessary to convert norepinephrine to epinephrine.

Familial pheochromocytoma is a component of two autosomal dominant syndromes: von Hippel–Lindau syndrome and multiple endocrine neoplasia (MEN) 2. Patients with von Hippel–Lindau

syndrome have pheochromocytoma (usually bilateral), retinal angiomas, cerebellar hemangioblastoma, epididymal cystadenoma, renal and pancreatic cysts, and renal cell carcinoma. Patients with MEN 2A develop pheochromocytoma (usually bilateral), medullary carcinoma of the thyroid (MTC), and primary parathyroid hyperplasia. Patients with MEN 2B develop pheochromocytoma (usually bilateral), MTC, mucosal neuromas, intestinal ganglioneuromatosis, and have a characteristic marfanoid body habitus. Pheochromocytoma also occurs in neurofibromatosis type 1 and familial paraganglioma. The frequency of pheochromocytoma in these disorders is 10% to 20% in von Hippel–Lindau syndrome, 50% in MEN 2, and 0.1 to 5.7% with neurofibromatosis type 1.

In some families, patients with pheochromocytomas have no other clinical abnormalities, suggesting the existence of a separate disease limited to the formation of adrenal medullary tumors. In a study of three generations of an affected kindred, a novel mutation was found in the von Hippel–Lindau gene even though there were no other clinical manifestations of this disorder. Patients with bilateral pheochromocytoma, young patients with pheochromocytoma, and patients with paraganglioma should be screened for MEN 2 and von Hippel–Lindau syndrome.

The etiology and pathogenesis of pheochromocytoma is unknown. A genetic component seems certain because pheochromocytoma occurs not only as a part of familial syndromes but also as an isolated disorder because of mutation in the RET gene or the MEN 2 gene. Familial pheochromocytoma as well as sporadic pheochromocytoma occurs also with mutations in the succinate dehydrogenase complex, subunit B, iron–sulfur protein (SDHB). Either germline or somatic mutations in the SDHB gene is another cause of pheochromocytoma (2).

Signs and Symptoms

Symptoms of pheochromocytoma are attributable to the effects of excessive circulating catecholamines on target tissues ([Table 77-3](#)). The classic triad of symptoms in patients with a pheochromocytoma is episodic headache, sweating, and tachycardia. Hypertension is common with pheochromocytoma and is sustained in roughly half of patients, is paroxysmal in one-third, and is absent in one-fifth. Orthostatic hypotension results from diminished plasma volume and blunted autonomic reflexes. Other symptoms include palpitations, anxiety, and tremulousness. Cardiovascular sequelae include myocardial infarction, cardiac dysrhythmias, and stroke. Gastrointestinal motility is also impaired. Asymptomatic patients with functioning tumors are rare, and nonfunctioning tumors are distinctly uncommon. Sudden death has been reported in patients with pheochromocytoma who have undergone surgical procedures or childbirth.

Diagnosis

Elevation of catecholamines and their metabolites in either urine or blood is essential for the diagnosis of pheochromocytoma. Either a 24-hour urine collection for catecholamines and their metabolites (metanephrines) or plasma-fractionated metanephrines can be used to make the diagnosis. Urine catecholamines/metanephrines are the most reliable tests with a sensitivity and specificity of 98%. Plasma fractionated metanephrines is similarly sensitive (99%), but lacks specificity (85%). Accordingly plasma fractionated metanephrines should be reserved for patients with a high pretest probability for pheochromocytoma – adrenal incidentalomas, classic symptoms, family history or genetic syndromes associated with pheochromocytoma (MEN etc.) while urine catecholamines/metanephrines are useful as screening tests for patients who are less likely to have a pheochromocytoma. Measurement of plasma catecholamines is not as useful in distinguishing patients with pheochromocytoma from those with essential hypertension. Measurement of plasma chromogranin A is nonspecific and a poor diagnostic but potentially helpful confirmatory test.

Many medications alter or interfere with measurement of either plasma or urine catecholamines. Such medications should be discontinued to ensure accurate testing. These drugs include acetaminophen, labetalol, clonidine withdrawal, tricyclic antidepressants, antipsychotics and ethanol. To control blood pressure, other antihypertensives such as calcium channel blockers may be substituted.

In normotensive or mildly hypertensive patients with elevated plasma catecholamine levels (1,000 to 2,000 pg/mL), a clonidine suppression test may be used to distinguish from pheochromocytoma. An oral 0.3-mg dose of clonidine suppresses centrally mediated release of catecholamines to less than 500 pg/mL within 2 to 3 hours but does not affect release of catecholamines by a pheochromocytoma.

Biochemical confirmation of the diagnosis should be followed by radiologic evaluation to locate the tumor. Pheochromocytomas are best imaged with CT or MRI. Contrast-enhanced CT readily detects tumors 1 cm and larger and has sensitivity of 87% to 100% for pheochromocytoma ([Fig. 77-10A](#)). MRI is similarly sensitive, and a T2-weighted image brightness three times greater than liver is highly

specific for pheochromocytoma (Fig. 77-10B,C). MRI is useful in suspected malignant pheochromocytoma to evaluate for inferior vena cava thrombus or liver invasion.

Functional nuclear imaging with iodine-131-metaiodobenzylguanidine (^{131}I MIBG) is a useful adjunct to cross-sectional imaging for pheochromocytoma (Fig. 77-10D). MIBG resembles norepinephrine and is taken up by adrenergic tissues including pheochromocytoma. An MIBG scan can detect tumors not detected by CT or MRI or multiple tumors when CT or MRI is positive. Multi-institutional experience with this technique has demonstrated an overall sensitivity of 77% to 87% and a specificity of 96% to 100%. This test is usually not necessary for sporadic pheochromocytoma unless urinary or plasma catecholamines and metabolites are marginally elevated, or if malignant or extraadrenal pheochromocytoma is suspected. ^{131}I MIBG scanning is also useful to screen patients with metastatic pheochromocytoma for high-dose ^{131}I MIBG therapy. ^{111}In -pentetretotide scintigraphy may also identify pheochromocytoma and can be used therapeutically as with ^{131}I MIBG.

Figure 77-10. Imaging of pheochromocytoma (arrows). **A:** Computed tomography scan shows well-circumscribed left adrenal mass. **B:** T2-weighted magnetic resonance imaging shows the mass to be heterogeneously bright, consistent with pheochromocytoma. **C,D:** Coronal contrast enhanced MRI and near-simultaneous ^{131}I -metaiodobenzylguanidine (^{131}I -MIBG) scanning show location of the pheochromocytoma and relationship to surrounding structures.

Treatment

Surgical resection is the only cure for pheochromocytoma. When the diagnosis of pheochromocytoma has been established and localization studies are completed, preoperative preparation of the patient centers on blood pressure control. Usually 1 to 3 weeks before operation alpha-adrenergic blockade is performed first with phenoxybenzamine, starting at 10 mg twice a day and increasing by 10 to 20 mg per day until blood pressure normalizes. Side effects of alpha blockade include postural hypotension, reflex tachycardia, nasal congestion, and an inability to ejaculate. Preoperative alpha blockade also

reverses the relative hypovolemia that is usually present in patients with pheochromocytoma and also prevents severe blood pressure swings during intraoperative manipulation of the tumor. Metyrapone added preoperatively to phenoxybenzamine can achieve a greater degree of sympathetic blockade.

Beta-adrenergic blockade with propranolol added after alpha blockade can manage patients who develop tachycardia or who have inducible cardiac arrhythmias or ischemia. Propranolol may enhance pressor response to endogenous norepinephrine and thus should not be given until adequate alpha blockade has been established. Propranolol can also produce profound bradycardia, myocardial depression, and congestive heart failure. Newer drug regimens to manage hypertension in pheochromocytoma include selective alpha-1-adrenergic antagonists (terazosin and doxazosin) and calcium channel blockers (nifedipine and nicardipine).

Patients with pheochromocytoma can be expected to have blood pressure volatility and high intravascular volume requirements during and immediately after surgery. Elderly patients or those with history of heart disease may require pulmonary catheter insertion and arterial line placement for careful monitoring of blood pressure and arterial pH. Anesthetic agents may trigger the release of catecholamines from pheochromocytomas. The anesthetic plane is now considered more important than the choice of agent, and both enflurane and isoflurane have been used successfully. Magnesium administration during surgery is an effective way to control blood pressure in patients with pheochromocytoma. Intraoperative hypertension is best treated with a sodium nitroprusside drip, and cardiac arrhythmias are best managed with short-acting beta-blockers (esmolol) or lidocaine.

Formerly, an anterior approach through either a midline or bilateral subcostal incisions was used exclusively to resect pheochromocytomas. Today, CT, MRI, and nuclear scans permit preoperative localization of tumor in 95% or more of cases, so that the surgical approach may be more directed using a laparoscopic approach. Regardless of approach, important common principles include minimal handling of the tumor, early isolation and ligation of the adrenal vein, and avoidance of capsular rupture. Recurrence following resection of benign pheochromocytoma is infrequent, and its presence indicates malignancy.

Recurrent, malignant pheochromocytoma can include locally advanced disease or metastasis to bone, liver, lymph nodes, lungs, and the central nervous system. Treatment of malignant pheochromocytoma involves resection of metastases when feasible and medical control of hypertension. Radiation therapy may be helpful to ameliorate pain from bony metastases. Ablative therapy with ¹³¹I MIBG may also produce partial responses and palliation of hormonal symptoms. Radiofrequency ablation of hepatic and bone metastases can be effective in selected patients. Combination chemotherapy with cyclophosphamide, vincristine, and dacarbazine can also be effective. Overall 5-year survival for patients with malignant pheochromocytoma ranges from 36% to 60%.

Metastasis to the Adrenal Glands

The adrenal glands are frequent sites for metastases from many cancers. Carcinoma of the lung and breast account for most adrenal metastases; however, virtually any cancer including melanoma, lymphoma, and kidney and ovarian carcinoma can spread to the adrenals. Autopsy series of patients with carcinoma show that the adrenal glands are involved in more than 25% of cases. Among cancer patients, 50% to 75% of newly discovered adrenal masses represent metastases. Usually, either a primary site is obvious, or widespread disease is apparent. Biopsy of adrenal masses in patients with a history of carcinoma may be performed after pheochromocytoma is excluded. Resection of isolated adrenal metastases in select patients with long disease-free intervals from lung cancer, renal cell carcinoma and melanoma can be considered, although subsequent extraadrenal disease usually develops. Median survival after complete resection of isolated adrenal metastases from a variety of tumors ranges from 13 to 60 months with actuarial 2- and 5-year survival of 40% to 50% and 20%, respectively.

Incidental Adrenal Mass

9 Clinically inapparent adrenal masses (also called *adrenal incidentalomas*) have become commonplace over the past 20 years with the increased use of abdominal imaging such as CT and MRI. The estimated prevalence of incidental adrenal neoplasms varies by population studied and method of detection. Unsuspected adrenal masses are detected by CT in between 0.6% and 1.9% of healthy patients, a figure that is somewhat lower than the estimated prevalence of up to 8.7% based on unselected autopsy data. Patients with a prior history of malignancy have a prevalence of adrenal masses of up to 4.4%. Adrenal masses increase in frequency with advancing age, ranging from 3% in midlife to 10% in the elderly. The combination of an aging population and increased application of abdominal imaging promises to create

a significant public health challenge.

Over the past 10 years, increased awareness of morbidity associated with subclinical hormone overproduction as well the increased availability of minimally invasive, laparoscopic adrenalectomy has resulted in a lower threshold for treatment of adrenal masses. The goal of evaluation is to distinguish and remove those adrenal masses that are functioning or likely to be malignant versus those that are neither and may be observed.

Expectations of the yield for the workup of adrenal masses may be informed by epidemiologic reports and reports of pathologic findings in resected incidentalomas. Epidemiologic data indicate that up to 6.5% of incidentalomas are pheochromocytoma, 7% produce aldosterone, 0.035% produce cortisol, and 0.06% is carcinoma. A recent review of 44 reports describing over 3,000 such cases reported that 41% were cortical adenomas, 19% were metastases from other primary cancers, 10% were adrenocortical carcinomas, and 8% were pheochromocytomas, with the remainder including myelolipomas and cysts.

Diagnosis

The evaluation of incidental adrenal masses, previously considered controversial, can now be standardized. Two simple questions must be answered: Is it functional? Is it malignant? The diagnostic approach should proceed to answer these questions sequentially (Table 77-6). Current opinion is that all asymptomatic patients with adrenal masses should be screened for pheochromocytoma, hypercortisolism, and hyperaldosteronism (Algorithm 77-3).

Table 77-6 Diagnosis Summary of Tests for Evaluation of Incidental Adrenal Mass

Question	Best Test	Alternative Test	Diagnosis
Is it functioning?	Plasma-fractionated metanephrines	24-hr urine for catecholamines, metanephrines, VMA	Pheochromocytoma
	1 mg dexamethasone suppression test		Hypercortisolism
	Serum potassium	24-hr urine for cortisol	Hyperaldosteronism
	Plasma renin/plasma aldosterone ratio	24-hr urine for potassium	
Is it malignant?	Computed tomography	Magnetic resonance imaging	Cortical adenoma
			Adrenocortical
			Carcinoma
			Pheochromocytoma
			Myelolipoma
			Cyst
	Fine-needle aspiration		Metastasis

All patients require a complete history and physical examination, biochemical evaluation of pertinent hormones, and select imaging studies. Attention must be paid to episodes of hypertension, tachycardia, and anxiety that suggest pheochromocytoma. Physical findings such as muscle wasting, purple striae, hirsutism, and gynecomastia may suggest either Cushing syndrome or a virilizing tumor. Secondary metastases from underlying malignancy must be considered and evaluated with appropriate history, physical examination, and select tests including mammograms in women and chest radiography in all patients, especially smokers.

Biochemical testing should routinely exclude pheochromocytoma, hypercortisolism, and hyperaldosteronism. Pheochromocytoma is evaluated either by 24-hour urine collection for catecholamines, metanephrines, and 3-methoxy-4-hydroxy-mandelic acid, or by plasma fractionated metanephrines. Subclinical or clinically apparent Cushing syndrome is best evaluated with the overnight 1 mg dexamethasone suppression test. Hyperaldosteronism is best assessed by concurrent measurement of serum or plasma aldosterone and PRA.

Imaging studies usually include cross-sectional imaging with either CT or MRI. CT is the best test for identifying and characterizing most adrenal masses. Using a fast scanner and 1-m scanning intervals, both adrenal glands can be identified in 97% to 99% of patients and lesions as small as 5 mm can be readily identified. Currently, attenuation values expressed in Hounsfield units (HU) have better performance than size or other criteria to differentiate adenomas from adrenal malignancy and nonadenomas such as pheochromocytoma. Adenomas are usually lipid rich and have attenuation values less than 18 HU on unenhanced CT, a threshold with high sensitivity and specificity (85% to 95% and 93% to 100%, respectively). Generally, further workup is unnecessary when an adrenal lesion has an attenuation of less than 10 HU suggesting lipid-rich adrenal adenoma. A notable exception is lipid poor adenoma, which has higher HU density. In these cases, rapid washout of intravenous contrast suggests an adenoma. Using a 10- to 15-minute delayed enhanced CT, a washout value of 50% to 60% of the

initial enhancement is used to distinguish adenoma from nonadenoma.

MRI can differentiate adenomas, metastases and pheochromocytomas, although the best MRI technique for evaluating adrenal masses is complex and controversial. Adenomas usually show a loss in signal intensity on chemical shift MRI because of high lipid content. Malignant masses tend to be bright on T2-weighted images because of higher fluid content. Secondary metastases to the adrenal are hypointense to liver on T1-weighted images and are brighter than liver on T2-weighted images. Metastases also typically show strong contrast enhancement. Pheochromocytomas most often have low lipid content and high water content, giving low T1 signal intensities and very bright T2 signal intensities. Comparison of the adrenal mass to liver and spleen intensities on various sequences adds to specificity and sensitivity of the test.

Algorithm 77-3. Diagnosis and management of the incidental adrenal mass. PRA, plasma renin activity; PAC, plasma aldosterone concentration; HTN, hypertension; CT, computed tomography; MRI, magnetic resonance imaging; FNA, fine-needle aspiration.

Masses that appear cystic may be aspirated under CT guidance. Fine-needle aspiration biopsy may be of value in patients with known extraadrenal malignancy; however, it is not indicated in the evaluation of primary adrenal neoplasms and is contraindicated if pheochromocytoma is suspected.

Treatment

Resection is indicated for all functioning adrenal incidentalomas and those suspected of harboring primary adrenal cancer. Size cutoff for resecting adrenal incidentalomas has drifted to include smaller and smaller lesions. The prevalence of primary adrenal carcinoma in adrenal incidentalomas is related to mass size. The risk of primary adrenal carcinoma is less than 2% in lesions under 4 cm while the incidence rises to 25% for lesions larger than 6 cm. Lesions larger than 6 cm and smaller lesions with suspicious criteria on imaging should be resected. Lesions smaller than 4 cm with benign imaging characteristics should be followed. For lesions between 4 and 6 cm, either resection or observation is acceptable. Decisions should not be based on size alone, but also on imaging characteristics including CT attenuation values. Resection of secondary adrenal malignancy is not generally recommended except for highly select patients.

Adrenal Insufficiency

Adrenal insufficiency reflects inadequate glucocorticoid and mineralocorticoid production by the adrenals, either secondary to suppression of the HPA axis or by destruction or removal of the adrenal glands. The most common causes of primary adrenal insufficiency are autoimmune adrenalitis, infection, and gland replacement with metastatic disease. Chronic exogenous steroid use with HPA suppression and surgical resection of adrenal glands are important causes of secondary adrenal insufficiency.

Clinical signs and symptoms usually do not become manifest until at least 90% of the gland is destroyed. Adrenal insufficiency usually occurs gradually unless the patient experiences stress which may precipitate acute crisis.

Signs and Symptoms

Acute adrenal insufficiency usually manifests as shock in a patient with undiagnosed chronic adrenal insufficiency who has been subjected to physiologic stress. Similarly, patients with established adrenal insufficiency caused by exogenous steroid use may experience crisis if they do not increase glucocorticoid replacement during times of stress or illness. Symptoms of adrenal insufficiency reflect glucocorticoid and mineralocorticoid deficiencies. Signs and symptoms of acute insufficiency include fever, nausea, vomiting, refractory hypotension, and lethargy (Table 77-7). Acute adrenal insufficiency is a medical emergency and should be suspected in stressed patients with a history of either adrenal insufficiency or exogenous steroid use. Chronic adrenal insufficiency presents more subtly, with fatigue, weight loss, anorexia, nausea and vomiting, abdominal pain, and diarrhea.

Diagnosis

Laboratory findings of adrenal insufficiency include hyponatremia, hyperkalemia, azotemia, and fasting or reactive hypoglycemia. Hypercalcemia may also be present. The rapid ACTH stimulation test is the best test for both acute and chronic adrenal insufficiency. Synthetic ACTH (250 µg) is administered intravenously, and plasma cortisol levels are measured 30 and 60 minutes later. Normal peak cortisol response should exceed 20 µg/dL. Measurement of ACTH by IRMA is then used to distinguish primary from secondary and tertiary adrenal insufficiency. High plasma concentration of ACTH (>200 pg/dL) and low plasma cortisol (<10 mg/dL) are diagnostic of primary adrenal insufficiency. Low levels of plasma ACTH indicate secondary (pituitary) or tertiary (hypothalamic) adrenal insufficiency.

DIAGNOSIS

Table 77-7 Symptoms and Signs of Acute Adrenal Insufficiency

Symptoms
■ Lethargy ■ Confusion or disorientation ■ Nausea and vomiting ■ Abdominal pain
Signs
■ Hypotension ■ Hyponatremia, hyperkalemia, azotemia, ■ Hypoglycemia ■ Fever ■ Anemia

Treatment

Acute adrenal insufficiency is based on clinical suspicion before laboratory confirmation is available. Intravenous volume replacement with isotonic fluids and immediate intravenous steroid replacement therapy with 4 mg dexamethasone is essential. A rapid ACTH stimulation test is then performed to establish the diagnosis of adrenal insufficiency after resuscitation and corticosteroid replacement. Hydrocortisone acetate is detected in laboratory measurement for cortisol so dexamethasone should be used for replacement of glucocorticoid function until ACTH testing is complete. Thereafter, 100 mg of hydrocortisone is administered intravenously every 6 to 8 hours and is tapered to standard replacement doses as the patient’s condition stabilizes. Mineralocorticoid replacement is not required until oral intake resumes. Chronic adrenal insufficiency requires both corticosteroid and mineralocorticoid replacement. Usual daily dosing is 12 mg/m² of hydrocortisone and 0.05 to 0.10 mg fludrocortisone.

Patients who have known adrenal insufficiency or who have received supraphysiologic doses of corticosteroid for at least 1 week in the year preceding surgery should receive perioperative stress-dose corticosteroids. Administration of 100 mg hydrocortisone the morning of major surgery followed by 100 mg of hydrocortisone every 8 hours during the perioperative 24 hours is usually more than sufficient. Steroids can be rapidly tapered to replacement levels as the patient’s condition permits.

ADRENALECTOMY

Surgical approaches to the adrenal glands include the laparoscopic approach, the anterior transabdominal approach, and less commonly, the combined thoracoabdominal approach or posterior

retroperitoneal approach. Either adrenal gland can be removed using any of these approaches. The choice of approach depends on the suspected pathology, the size of the adrenal lesion, and the expertise of the surgeon. Small benign appearing tumors that are localized with confidence by imaging studies are resected using a laparoscopic or posterior approach. Posterior retroperitoneal adrenalectomy, once the most common method of adrenalectomy is less commonly used since most lesions amenable to this approach can be removed laparoscopically. Large adrenal masses and those that may harbor malignancy should be resected using an anterior approach to adequately explore the entire abdomen and gain sufficient exposure for safe resection. Very large adrenocortical carcinomas may require a thoracoabdominal approach for *en bloc* resection with involved adjacent structures. Recently, a retroperitoneal laparoscopic approach has been advocated as an alternative method for small tumors, particularly for patients with prior abdominal surgery.

Laparoscopic Adrenalectomy

Laparoscopic adrenalectomy is now the preferred approach to most small, benign adrenal lesions including functioning and nonfunctioning adenomas and pheochromocytomas. Enthusiasm for the laparoscopic approach is based on the expectation of decreased postoperative pain, faster rehabilitation, and fewer complications. Numerous studies have shown the efficacy and safety of this procedure for tumors up to 6 cm. Larger lesions can be approached by experienced surgeons in select circumstances. Importantly, expertise in open adrenalectomy is absolutely necessary for the laparoscopic surgeon to convert to an open procedure and promptly rectify any intraoperative laparoscopic complications.

Laparoscopic adrenalectomy begins with induction of general anesthesia, placement of a urinary catheter and orogastric tube, and positioning of the patient in the lateral decubitus position with the affected side up. Exposure is facilitated by extension of the operating table at the patient's waist. A total of three or four intraperitoneal ports (one camera, one retractor particular for the right side, and two working ports) are placed at least 5 cm apart in a transverse line from the lateral edge of the rectus sheath to the midaxillary line between the costal margin and iliac crest (Fig. 77-11A). Four-quadrant exploration of the peritoneal cavity is first performed with the videoscope through the medialmost port, and the videoscope is then transferred to the middle port. A retractor is placed through the medial most port to retract the viscera medially. Operating instruments are alternately placed within the abdomen through the lateral ports.

Laparoscopic adrenalectomy proceeds similar to the open anterior approach. Right adrenalectomy begins with mobilization of the liver to open the retroperitoneum and allow retraction of the right lobe of anteriorly and medially using the most medial port. The adrenal gland is then identified posterolateral to the inferior vena cava and superior to the kidney. Dissection usually begins by developing the plane between right adrenal and inferior vena cava using careful blunt dissection, with small vessels sequentially coagulated using electrosurgical or harmonic energy. The right adrenal vein is identified, carefully dissected and then doubly clipped and divided. Dissection then continues circumferentially around the gland with additional small vessels coagulated or clipped. The adrenal gland subsequently is placed in a bag and removed through an expanded port.

Left adrenalectomy is performed with mirror-image patient and port-site orientation as right adrenalectomy. After port placement, dissection begins with mobilization of the splenic flexure of the colon and spleen from the left retroperitoneum. Subsequent medial retraction of the spleen, tail of the pancreas, and stomach is accomplished with the fan or similar retractor if necessary. Often after full mobilization, no retractor is necessary, and thus only 3 ports are needed. The left adrenal gland is identified in perinephric fat at the superior renal pole. Intraoperative laparoscopic ultrasound can be useful for this on the left side, particularly in Cushing syndrome with the associated increased truncal fat. Once identified, left adrenal gland dissection proceeds circumferentially around the gland, with identification, ligation and division of the left adrenal vein at the inferiormost aspect of the dissection. Care is needed to identify and avoid the inferior phrenic vein, which courses along the medial aspect of the left adrenal gland. Following circumferential dissection, the gland is removed.

Anterior Approach

Anterior, open adrenalectomy begins with positioning the patient in reverse Trendelenburg position with elevation of the right flank. An ipsilateral or bilateral subcostal incision allows access to either adrenal and facilitates exploration of the abdomen (Fig. 77-11B). The abdomen is opened and explored for evidence of metastatic disease, including biopsy or excision of suspicious lesions. Resection of the right adrenal gland proceeds with full mobilization and anteromedial retraction of the right hepatic lobe

(Fig. 77-12A). It is important to fully expose the retrohepatic inferior vena cava. In order to uncover the inferior vena cava, the right kidney and the right adrenal gland, the hepatic flexure and transverse colon and are retracted inferiorly, usually without need for extensive mobilization. A Kocher maneuver of the duodenum is seldom necessary as the adrenal gland is superior to this area. The retroperitoneal space is entered behind the liver to expose the adrenal gland. Dissection of the gland proceeds from its inferomedial aspect, where small feeding arteries are individually clipped and divided. The vena cava is carefully dissected along its lateral border, which allows identification of the right adrenal vein where it drains directly into the inferior vena cava from the anterior aspect of the adrenal gland. The adrenal vein is ligated and divided close to the vena cava. If necessary because of hemodynamic changes during an operation for a pheochromocytoma, the adrenal vein is identified and ligated early to avoid catecholamine surges and blood pressure fluctuations during manipulation of the gland. Once the adrenal vein is ligated, arterial feeding vessels are clipped and divided sequentially, beginning at the superolateral aspect of the gland and continuing medially.

Resection of the left adrenal gland requires mobilization of the spleen, tail of pancreas and left colon. The left colon is freed from its peritoneal attachments and is reflected inferiorly. The spleen is then delivered from the left upper quadrant medially, and the splenocolic ligament is divided. The spleen, stomach, and pancreatic tail are retracted medially *en bloc* to expose the left kidney and adrenal (Fig. 77-12B). The left adrenal vein is ligated and divided at its junction with the left renal vein. The gland is dissected and the arterial vessels are ligated and divided sequentially, beginning at the superolateral aspect of the gland and continuing medially.

Thoracoabdominal Approach

The thoracoabdominal approach is used for large adrenal lesions with invasion of surrounding structures including the liver and diaphragm on the right side, and the spleen, pancreatic tail, stomach, and diaphragm on the left. The patient is positioned with the ipsilateral flank raised and arm extended cephalad. Incision is made in the tenth or eleventh intercostal space beginning at the posterior axillary line and is extended toward the midline of the abdomen (Fig. 77-11C). Retractors are placed and subsequent adrenalectomy is performed as for the anterior approach.

Posterior Approach

With the advent of laparoscopic adrenalectomy, the posterior approach is infrequently used. When laparoscopic adrenalectomy is not an option, typically because of extensive prior transperitoneal operations, the posterior approach is better tolerated and allows faster postoperative recovery compared with the anterior approach. A posterior approach becomes increasingly more difficult as tumor size increases and is not recommended for excision of large pheochromocytomas, adrenal tumors greater than 6 cm, or adrenal carcinoma.

Figure 77-11. Incisions for right adrenalectomy. Shown are typical incisions for (A) laparoscopic approach, (B) open, anterior approach, (C) thoracoabdominal approach, and (D) posterior, open approach. Incisions for left adrenalectomy are positioned opposite.

Figure 77-12. Anterior approach to right (A) and left (B) adrenalectomy. Note position of phrenic vein in relationship to the left adrenal vein and tumor.

The patient is placed prone on the operating table and flexed at the waist, which allows the abdominal contents to fall away from the retroperitoneum. The incision is made from the midline at the tenth rib and is extended inferolaterally to the superior border of the posterior iliac crest (Fig. 77-11D). Dissection proceeds through the subcutaneous fat and latissimus dorsi muscle to the lumbodorsal fascia. This fascia is incised longitudinally, and the underlying sacrospinalis muscle. The sacrospinalis muscle is

retracted medially, and the twelfth rib and vascular bundle are resected as far medially as possible. The twelfth intercostal nerve is preserved and gently retracted superiorly. The retroperitoneum is entered and the diaphragm is bluntly elevated from Gerota fascia, the pleura are separated from the diaphragm, and the diaphragm is then divided. Gerota fascia is incised, and the kidney is retracted inferiorly to expose the adrenal gland. The arterial blood supply is controlled first by clipping and ligating numerous arterial vessels, which course posteriorly. The adrenal vein, located deep to the arteries, is ligated as it is encountered. On the right, the adrenal vein exits from the anterior aspect of the gland and courses to the inferior vena cava. Once the adrenal vein is divided the gland is then freed circumferentially from its lateral to medial aspect. The inferior border of the gland is dissected last to maintain attachment to the kidney and allow inferior retraction of the gland. Finally, repair of the diaphragm and any incidental pleural defects, reapproximation of the lumbodorsal fascia, and closure of the skin.

Posterior Retroperitoneal Laproscopic Adrenalectomy

Posterior retroperitoneal laproscopic adrenalectomy also known as posterior retroperitoneoscopic adrenalectomy maintains the advantages of a laparoscopic approach while avoiding the abdominal cavity. This approach is ideal for patients with prior abdominal surgery or for bilateral adrenalectomy as both adrenal glands can be removed without repositioning the patient.

Posterior retroperitoneal laproscopic adrenalectomy begins with placing the patient in the prone jackknife position on a spinal table allowing the abdominal contents to hang forward. The hips and knees are positioned at 90-degree angles to the spine and femur and carefully padded. The first port is placed just below the tip of the 12th rib; after the incision is made the retroperitoneal space is entered sharply, a space is created bluntly with the index finger, and a blunt 10-mm trocar is placed. A second medial 10-mm trocar is placed along the paraspinous muscle at a 45-degree angle toward the adrenal gland. A lateral 5-mm port is placed 5 cm lateral to the first port in a similar fashion. Pneumoretroperitoneum to 20 to 24 mm Hg is created with CO₂ to create an adequate working space. The videoscope is transferred from the initial middle port to the medial port to complete the dissection. The retroperitoneal space beneath the diaphragm is created bluntly and sharply. The superior border of the kidney is immediately identified and Gerota fascia is entered. The upper pole of the kidney is retracted caudally and the tissue superior to the kidney which contains the adrenal gland is completely separated from the kidney. The medial dissection is then begun by carefully bluntly dissecting medial to the adrenal gland identifying the adrenal vein and dividing it between clips. Identification of the adrenal vein, particularly on the right side, is easier than with the transabdominal laparoscopic approach. Dissection is completed circumferentially around the gland using electrosurgical or harmonic energy to coagulate any small vessels. Once the gland is completely free, it is placed in a bag and removed through the middle port.

Chapter 78

Pituitary Surgery

Brooke Swearingen and Nicholas A. Tritos

Key Points

- 1 Clinical manifestations of sellar masses may include local mass effect, pituitary hormone excess or deficiency.
 - 2 Pituitary adenomas account for the vast majority (91% to 92%) of sellar lesions in surgical series, although the differential diagnosis is broad.
 - 3 Incidental sellar lesions are common findings on cranial imaging performed for unrelated indications.
 - 4 Despite recent advances in genetics and molecular biology, the pathogenesis of most sellar masses remains obscure.
 - 5 Thorough clinical, radiologic and endocrine testing can help significantly narrow the differential diagnosis before pituitary surgery.
 - 6 With the exception of many prolactin-secreting pituitary adenomas, transsphenoidal pituitary surgery remains first-line therapy for pituitary adenomas associated with mass effect or hormone excess.
 - 7 There are a number of surgical techniques and approaches in current use with similar outcomes; the trend is toward increasing use of endoscopy.
 - 8 Medical therapy is generally considered first-line treatment in patients with prolactin-secreting pituitary adenomas.
 - 9 Medical therapy has an adjuvant role in patients with other secretory adenomas (acromegaly, Cushing disease) who are not cured after pituitary surgery.
 - 10 Management of pituitary adenomas is best delivered in a multidisciplinary setting, where the multiple treatment options available can be individualized to a given patient.
-

INTRODUCTION

1 The pituitary, as the “master gland,” is responsible for the control of much of the body’s endocrine function. Directly or indirectly, it affects the function of the thyroid, adrenals, and ovaries or testes, and regulates growth, lactation, and ovulation. Its posterior lobe helps to regulate water homeostasis and parturition. Surgical disorders of the pituitary can manifest as either an endocrinopathy, with syndromes of hypo- or hypersecretion of necessary hormones, or as abnormalities caused by mass effect, especially visual field deficits, related to its anatomic location. This chapter will review the basic anatomy and endocrine physiology of the gland, as well as the diagnosis, imaging, and pathology of pituitary disorders and describe the surgical management in the setting of multidisciplinary treatment options.

ANATOMY

The pituitary lies within a bony cavity in the posterior sphenoid bone, the sella turcica, or “Turkish saddle.” Anatomic boundaries are formed anteriorly and inferiorly by the sphenoid sinus, posteriorly by the dorsum sella and posterior clinoids, anterosuperiorly by the tuberculum sella, and superiorly by the diaphragm sella, a thin dural reflection over the superior margin of the gland (Fig. 78-1A,B). The lateral boundaries are formed by the cavernous sinuses. The gland itself is composed of an anterior, intermediate, and posterior lobe (the adenohypophysis, pars intermedia, and neurohypophysis or pars nervosa, respectively). Embryologically, the gland is derived from the apposition of stomodeal ectoderm (anterior lobe) and neuroectoderm (posterior lobe). The anterior lobe consists of a pars

distalis, within the sella, and pars tuberalis, along the anterior infundibulum, which penetrates the diaphragm sella and connects the gland to the hypothalamus. The vascular supply is formed by the inferior hypophyseal arteries arising bilaterally from the intracavernous carotids, and supplying the neurohypophysis, and the superior hypophyseal arteries, which supply the median eminence and infundibulum as well as forming the capillary network of the hypophyseal-portal system. This portal system carries hypothalamic releasing hormones along the infundibulum to the anterior lobe. Venous drainage leaves through the cavernous and superior and inferior petrosal sinuses bilaterally and thence to the transverse sinuses and internal jugular veins. There is often a variably developed dural venous sinus, the circular sinus, usually at the level of the tuberculum sellae, connecting the two cavernous sinuses, and there may be dural venous plexi of variable size and location beneath and posterior to the sella.

Important anatomic relationships, both in terms of pathologic effects and surgical approach, include the laterally placed cavernous sinuses, and superiorly the suprasellar cistern, through which course the optic nerves and chiasm. The cavernous sinuses are formed by venous drainage from the ophthalmic veins, middle and inferior cerebral veins, and sphenoparietal sinuses. Traversing structures include the intracavernous carotid artery, and multiple cranial nerves, including cranial nerve III (oculomotor), cranial nerve IV (trochlear), the ophthalmic branch of the trigeminal (V1), and the maxillary branch of the trigeminal (V2). These nerves travel in the dural reflection which forms the lateral wall of the cavernous sinus, from superior to inferior. The VIth cranial nerve (abducens) runs along the lateral aspect of the intracavernous carotid. Nerves III, IV, VI, and V1 exit into the superior orbital fissure, while V2 exits through the foramen rotundum. The optic nerves and chiasm travel above the gland, within the suprasellar cistern. Superior extension of the sellar contents, for example, from a pituitary neoplasm, can compress the chiasm from below, leading to visual abnormalities. Axons from the nasal retinal ganglion cells (which receive input from the ipsilateral temporal visual fields) cross in the chiasm en route to the opposite occipital cortex. Compression of these crossing fibers at the level of the chiasm leads to a bitemporal hemianopsia, pathognomonic of a sellar mass.

PATHOLOGY OF SELLAR LESIONS

Pituitary Adenomas

2, 3 Pituitary adenomas are the most common tumors of the sella and most important surgical pathology, but the differential diagnosis of sellar lesions is broad (Tables 78-1 and 78-2). The true incidence of adenomas is difficult to determine as it varies depending on whether the series is based upon clinically significant tumors, autopsy findings, or imaging data. The prevalence of incidental sellar masses found in imaging studies is about 10% to 22%, while it is about 14% in autopsy series.¹ The original pathologic classification was based upon staining affinity for histologic dyes, that is, acidophilic, basophilic, or chromophobe. A more recent and clinically useful pathologic classification from the WHO is based upon immunocytochemistry of various hormone subtypes. These include:

Prolactinomas (Lactotroph Adenomas)

Although less important in surgical series since the advent of dopamine agonist treatment, these are one of the most common pituitary adenomas with an incidence of 6 to 10 per million per year and a prevalence of 60 to 100 cases per million.² Also known as lactotroph adenomas, they arise from the prolactin-secreting cells of the adenohypophysis. They are commonly microadenomas in women, but

especially in men may become large and invasive.

Table 78-1 Tumors of the Pituitary

Pituitary adenomas

Secondary tumors

From DeLellis RA, Lloyd RV, Heitz PU, Eng C, eds. World Health Organization classification of tumors: Tumors of endocrine organs. IARC: Lyons; 2004.

Growth Hormone-Secreting Adenomas (Somatotroph Adenomas)

These tumors secrete excess levels of growth hormone, leading to gigantism in children and acromegaly in adults. The incidence of acromegaly is about 2 to 4 cases per million per year.³ These tumors may sometimes coexpress prolactin (mammosomatotroph adenomas) and rarely TSH, as these cellular subtypes appear to arise from a common stem cell origin. They are typically invasive macroadenomas.

ACTH-Secreting Adenomas (Corticotroph Adenomas)

These tumors secrete excess levels of ACTH, leading to excess production of cortisol by the adrenal glands (Cushing disease). They are uncommon, with an estimated incidence of 1.2 to 1.7 cases per million per year.⁴ Pathologic diagnosis can be difficult, given that these tumors are often quite small and surgical specimens limited. Corticotroph adenomas typically manifest loss of normal glandular architecture, with positive immunocytochemistry for ACTH.

TSH-Secreting Adenomas (Thyrotroph Adenomas)

These tumors are uncommon and typically comprise less than 1% of surgical series. Patients will sometimes present with hyperthyroidism, but TSH staining without clinical hyperthyroidism is a more common scenario.⁵

Gonadotroph Adenomas

These tumors are common and comprise most of the “nonfunctioning” adenomas, as they express primarily hormone subunits, including beta FSH, LH, or alpha subunits. They become symptomatic via mass effect, with compression of normal gland leading to pituitary hypofunction, or compression of the chiasm leading to visual field abnormalities. Very rarely, patients with these tumors may present with symptoms attributed to excess gonadal steroids, such as precocious puberty, irregular menses, or psychiatric manifestations.

Null Cell Adenomas

These tumors are uncommon; they manifest no clinical or immunocytochemical evidence of hormone secretion, but this may be a function of the sensitivity of the immunocytochemical technique.

“Atypical” Adenomas and Pituitary Carcinomas

Pituitary carcinoma is extraordinarily rare. It is defined by the presence of distant metastases or CSF dissemination. While pituitary carcinomas may demonstrate extensive pleomorphism and/or necrosis, these pathologic findings are also seen in benign adenomas. The factors correlated with aggressive clinical behavior include an elevated Ki-67 labeling index (MIB-1 fraction, proliferation index) and extensive p53 reactivity.⁶ “Atypical” adenomas have been defined as those tumors manifesting an MIB-1 fraction of greater than 3%, excessive p53 immunoreactivity, and increased mitotic activity.⁷ Atypical adenomas are usually larger and invasive, but are not uncommon (15% in some surgical series), and the factors predisposing to malignant degeneration and metastasis are not well defined.⁸

Nonadenomatous Lesions of the Sella

Although pituitary adenomas are the most common neoplasms of the sella, a variety of other lesions can occur (Table 78-2).^{9,10}

Neoplasms

Other neoplasms of the sella are uncommon but remain important in the differential diagnosis. *Craniopharyngiomas* are benign, solid, or partially cystic masses which presumably arise from remnants of Rathke pouch.¹¹ They occur in a bimodal distribution with peaks in childhood and in older adults. The adamantinomatous type is typical in children, and is often cystic and partially calcified. The cysts contain a “motor oil” appearing fluid, which can produce severe chemical meningitis when in contact with the CSF. The epithelium produces keratinaceous debris and cholesterol clefts. There is often a pronounced inflammatory reaction. The papillary type is seen almost exclusively in older adults. It may be cystic and/or solid, and can be densely adherent to surrounding neural structures, especially the optic nerves and hypothalamus. *Meningiomas* can arise anywhere along the intracranial dura, including within the sella. Meningiomas arising from the diaphragm sella or tuberculum sella can mimic pituitary adenomas and lead to endocrine dysfunction and chiasm compression. *Germ cell tumors* are most common in children and young adults and occur predominantly in males. The sella is the second most common location after the pineal; the most common subtype is the germinoma followed by teratomas. *Metastases* to the sella are fortunately rare, most commonly from breast and lung.¹²

Cysts

A variety of nonneoplastic cysts can occur within the sella. Although most are incidental findings seen on routine MRI imaging, large cysts can sometimes lead to endocrine dysfunction or chiasm compression. The most common cystic structure is *Rathke cleft cyst*, arising from a remnant of Rathke pouch within the pars intermedia. Rathke cysts can sometimes enlarge with time and compress surrounding structures; they may then require drainage and/or resection. Most, however, are incidental findings, and require no treatment. *Epidermoid* or *dermoid* cysts arise from ectopic squamous or dermoid tissue and can fill with keratinaceous debris. *Arachnoid* cysts are CSF containing structures which may also occur within the sella, presumably arising by means of a “one-way valve” mechanism allowing CSF to enter the cyst cavity but not exit; enlarging cysts may become clinically symptomatic.

Inflammatory Lesions

Inflammatory lesions of the sella are rare. *Lymphocytic hypophysitis*, the most common, is thought to represent an autoimmune phenomenon and is seen usually in women during or after pregnancy, often in association with other autoimmune disorders (Hashimoto thyroiditis, atrophic gastritis.) The gland is enlarged and infiltrated with inflammatory cells and pituitary dysfunction may occur. *Granulomatous hypophysitis* can arise from infections, that is, tuberculosis or fungal, or idiopathic granulomatous inflammation, either alone or in association with sarcoidosis. The recent introduction of ipilimumab antibody therapy for melanoma has led to the recognition of a presumed immune-mediated hypophysitis associated with pituitary enlargement and dysfunction.¹³ Other uncommon types of hypophysitis include xanthomatous, necrotizing, and IgG4 related.

MOLECULAR PATHOGENESIS

4 The molecular pathogenesis of pituitary adenomas remains unclear, although a number of possibilities have been suggested.^{14,15} The majority of pituitary adenomas are monoclonal in origin.^{16,17} The adenoma presumably arises from a single mutated cell, but the relative contributions of intrinsic genetic events and stimulation by hypothalamic hormones and local growth factors remain to be determined. Progression to malignancy with metastasis is rare, although local invasion is common. Genetic mutations predisposing to the development of pituitary adenomas include mutations in the *AIP* gene (aryl hydrocarbon receptor interacting protein) which has been found in some familial pituitary adenoma cohorts as well as some sporadic adenomas, especially in young acromegalic patients. The *MEN1* (multiple endocrine neoplasia) gene is also associated with familial adenomas, but is uncommon in sporadic disease, as is the *GNAS* mutation associated with McCune Albright syndrome. The *PRKAR1A* gene encodes a type 1A regulatory subunit of protein kinase A. Inactivating mutations of this gene are identified in 60% to 70% of patients with Carney complex, a condition of dominant inheritance, which may lead to acromegaly as a result of somatotroph hyperplasia or adenoma, as well as a variety of extrapituitary manifestations. Epigenetic modification has been suggested as a mechanism to influence gene expression without alteration in the underlying genome. Altered expression of genes encoding CDKN2A (cyclin-dependent kinase inhibitor), DAPK (death-associated protein kinase), FGFR2 (fibroblast growth factor receptor 2), among others, have been associated with sporadic pituitary adenomas. Loss of tumor suppressor genes may also be involved in adenoma pathogenesis. Loss of the *GADD45* gene expression occurs in the majority of human pituitary adenomas, and products of the *AIP*, *PRKAR1A*, and *MEN1* genes may also act as tumor suppressors, with loss of these products in familial syndromes predisposing to the development of pituitary adenomas, in a “two-hit” model. Dysregulation of micro RNAs, which can regulate translation of target mRNAs, has recently been found in pituitary adenomas, and differential expression can be associated with specific tumor subtypes. It is unclear which, if any, of these abnormalities are primary as opposed to epiphenomena in pituitary tumorigenesis.

ENDOCRINE EVALUATION

5 All patients with a pituitary mass require endocrine evaluation for pituitary hypofunction, and patients with possible pituitary adenomas require evaluation for hypersecretory syndromes as well. This is best done in conjunction with an endocrinologist experienced in the management of pituitary disease.

Pituitary Hypofunction (Hypopituitarism)

It is important to determine the presence of hypopituitarism, especially in patients requiring surgical treatment, as unrecognized hypothyroidism or hypoadrenalism may have a profound effect on response to anesthesia and complicate recovery from surgery. Determination of anterior pituitary dysfunction requires measurement of free thyroxine (free T4) and thyrotropin (TSH), gonadal hormones (estradiol and testosterone), as well as gonadotropins (LH and FSH), basal and stimulated cortisol levels, and sometimes growth hormone levels and IGF1 (insulin-like growth factor 1) if clinically indicated. Central (secondary) hypothyroidism is characterized by low free T4 levels in association with low or inappropriately normal TSH. Central hypogonadism is characterized by low morning testosterone levels in men, and low estradiol levels in women, associated with low or inappropriately normal FSH and LH. Central hypoadrenalism is characterized by low morning cortisol levels in association with low or inappropriately normal ACTH. Morning serum cortisol ≤ 3 mcg/dL is diagnostic of adrenal

insufficiency, whereas morning serum cortisol ≥ 18 mcg/dL assures sufficient adrenal function. Intermediate cortisol levels are indeterminate with regard to adrenocortical function and require further evaluation, including stimulation with cosyntropin or insulin tolerance testing. Growth hormone levels are normally pulsatile, which can make growth hormone insufficiency difficult to diagnose; it can be presumed in the presence of multiple hormone insufficiencies, and confirmed by appropriate stimulation testing, which can be undertaken after definitive treatment of the underlying pituitary lesion and replacement of other pituitary hormone deficiencies have been implemented. Replacement therapy, especially levothyroxine and glucocorticoid (prednisone or hydrocortisone), should be considered as soon as the diagnosis of insufficiency is confirmed, especially in those patients who require surgery. Glucocorticoid replacement should precede thyroid hormone replacement in order to avoid precipitating adrenal crisis. Posterior pituitary dysfunction, typically diabetes insipidus (DI) is uncommon as a presenting symptom; when seen in association with sellar mass, the diagnosis is unlikely to represent a pituitary adenoma. Diabetes insipidus is characterized by polyuria/polydipsia, hyposthenuria and tendency to hyperosmolar dehydration if access to water is limited or thirst is deficient; confirmation may require a water deprivation test in uncertain cases. Hyponatremia may also occur in patients at the time of their initial presentation as a consequence of the syndrome of inappropriate antidiuretic hormone secretion (SIADH), central hypoadrenalism, or hypothyroidism.

Hypersecretory Syndromes

6 Pituitary adenomas may be associated with excess hormone secretion, giving rise to well-characterized clinical syndromes. It is important to recognize these preoperatively, especially since surgical treatment in some instances is not first-line therapy. In particular, patients with prolactin-secreting pituitary adenomas may be offered a trial of medical therapy, as dopamine agonists are effective in controlling tumor size and relieving mass effect.

Excess Prolactin (Prolactinomas)

Prolactin levels in women are physiologically increased during pregnancy, and are responsible for lactation; prolactin levels in healthy men are typically low. Excess prolactin in women leads to the syndrome of amenorrhea/galactorrhea, and hypogonadism with sexual dysfunction in men. Mildly elevated prolactin levels may be related to medication effects (dopamine antagonists, e.g., psychotropic medications), a microprolactinoma, or “stalk effect.” (Table 78-3). This phenomenon occurs from the loss of tonic dopamine inhibition on the lactotrophs of the pituitary by any nonspecific mass compressing the pituitary stalk. Thus a nonfunctioning tumor or other pituitary lesion of sufficient size can lead to a moderately elevated prolactin level, usually less than 200 ng/mL, and this must be distinguished from a prolactinoma, as treatments are potentially different. A large tumor in the setting of a mildly elevated prolactin level likely represents “stalk effect” rather than a true prolactinoma; a mildly elevated prolactin level in the setting of a microadenoma likely represents a true microprolactinoma. Caution is advised in the interpretation of prolactin levels in patients with large sellar masses. Giant macroprolactinomas may secrete prolactin exuberantly, giving rise to the “hook effect,” an immunoassay artifact that occurs in the presence of very high serum concentrations of prolactin, leading to substantial underreporting of prolactin levels. To avoid this artifact, prolactin should be measured in serially diluted serum specimens in patients with large sellar lesions.

Excess Cortisol (Cushing Syndrome)

Hypercortisolemia of any cause is known as “Cushing syndrome.” These patients may present with a wide variety of manifestations, including metabolic (central adiposity, glucose intolerance), catabolic (muscle wasting, increased fracture risk, skin thinning, spontaneous ecchymoses, increased risk of infection), cardiovascular (hypertension, thromboembolism, coronary artery disease), mineralocorticoid (edema, hypokalemia), hypogonadal, hyperandrogenic (hirsutism, acne), and psychiatric symptoms. There are a number of causes of Cushing syndrome, including (most commonly) iatrogenic, but important neoplastic causes potentially requiring surgical treatment include pituitary adenomas, adrenal adenomas/carcinomas, or the ectopic secretion of ACTH by a nonpituitary/adrenal source, usually carcinoid tumors or small cell lung cancers. Approximately 70% to 80% of patients with noniatrogenic causes of Cushing syndrome will have a pituitary adenoma (Cushing disease). The diagnosis of Cushing disease can be difficult, and is best performed by an endocrinologist experienced in pituitary evaluation. Hypercortisolemia is determined by measurement of 24-hour urine free cortisol levels, elevated serum cortisol levels on dexamethasone suppression testing, and, more recently, by elevated late-night salivary

cortisol levels. These tests help establish the presence of cortisol excess and differentiate between Cushing syndrome and other states associated with high cortisol levels (Table 78-4). ACTH dependence or independence is determined by the measurement of plasma ACTH levels; low ACTH levels (ACTH independence) is seen with adrenal disease, as the increased cortisol levels are secreted independently of central ACTH production, resulting in normal feedback inhibition of pituitary ACTH production. High or inappropriately normal ACTH levels (ACTH dependence) are seen with pituitary or ectopic sources. Normal ACTH levels in association with hypercortisolemia can also occur when diurnal variation is lost, and typically point to a central rather than adrenal source. Dexamethasone suppression testing can be performed to biochemically differentiate pituitary from ectopic sources. Classically, failure to suppress cortisol levels with high-dose dexamethasone is associated with an ectopic source, though this may also be seen with some pituitary macroadenomas. While pituitary MRI imaging may demonstrate an adenoma, typically the microadenomas of Cushing disease are very small, and may not appear on MRI in 30% to 40% of patients. In these cases confirmation of a pituitary source requires bilateral inferior petrosal sinus sampling, where ACTH levels obtained from the inferior petrosal sinuses (both before and after the intravenous administration of corticotropin-releasing hormone [CRH]) are compared to levels obtained in the vena cava; a central-peripheral ACTH ratio of greater than 3:1 after the administration of CRH is considered diagnostic of a central source, even in the absence of tumor visualization on MRI.¹⁸

Table 78-3 Causes of Hyperprolactinemia

Physiologic	Pathologic (Pituitary)	Pathologic (Other)
Pregnancy	Prolactin-secreting adenoma	Medications (e.g., risperidone, metoclopramide, tricyclics, opioids)
Lactation	Growth hormone and prolactin cosecreting tumor	Polycystic ovary syndrome
Food	Any sellar mass causing “stalk effect”	Primary hypothyroidism
Coitus	Empty sella	Renal failure
Nipple stimulation	Cranial irradiation	Chronic liver disease
Physical stress	Idiopathic	Chest wall lesions

Table 78-4 Conditions Associated with Cortisol Excess

Cushing Syndrome	Cortisol Excess in Patients with Some Manifestations of Cushing Syndrome (But No Tumor)	Cortisol Excess in Patients Without Manifestations of Cushing Syndrome
Pituitary adenoma (Cushing disease)	Depression	Acute illness, injury or surgery
Ectopic ACTH secretion	Alcohol dependence	Hospitalization
Adrenal tumor (adenoma, carcinoma) or hyperplasia	Severe obesity	Anorexia nervosa
Iatrogenic	Poorly controlled diabetes mellitus	High corticosteroid-binding globulin (CBG) levels
Surreptitious	Polycystic ovary syndrome Familial glucocorticoid resistance	

Excess Growth Hormone (Acromegaly)

Excess growth hormone secretion by a pituitary adenoma in childhood, prior to epiphyseal closure, leads to gigantism, while growth hormone excess in adulthood leads to acromegaly. Adult patients will typically report increased ring and shoe size, dental and jaw abnormalities with malocclusion, coarsening of facial features (often falsely attributed to aging), headache, hoarseness, skin tags, increased sweating, carpal tunnel syndrome, arthralgias, frequent snoring, and sleep apnea. Because these changes occur slowly over time, diagnosis can be delayed, and these tumors are often larger and invasive at the time of detection. Systemic changes include glucose intolerance or frank diabetes mellitus, hypertension, and cardiomyopathy. There is an increased risk of colon polyps, and possibly colon and thyroid cancer. Acromegalic patients have a mortality risk on the order of 2 to 3 times that of the general population, if growth hormone excess is not adequately controlled. Many of these changes are reversible with successful control of the disease, but skeletal abnormalities are not. Because growth hormone secretion is pulsatile, random growth hormone measurements are not diagnostic. IGF1

(somatomedin C) is a protein produced mostly in the liver in response to growth hormone levels over time; it acts to integrate the pulsatile growth hormone levels and serves as the best single indicator of disease activity. IGF1 assays are technically challenging and require gender and age adjustment, as growth hormone levels increase during childhood and adolescent development and decrease with aging, and are higher in males than females. Because growth hormone is physiologically suppressed by a glucose load, glucose-suppressed growth hormone levels have been used as an indicator of disease activity, since acromegalic patients fail to suppress and may paradoxically increase. The criterion for adequate suppression has varied with the available growth hormone assay; current best available assays require suppression to at least GH <1 ng/mL (ideally below 0.4 ng/mL). Growth hormone measurements over time (day curve) have also been used in diagnosis, but are cumbersome to determine in an outpatient setting.

TSH Adenomas

While immunocytochemical staining for TSH is not uncommon, secretion of active thyrotropin in excess leading to central hyperthyroidism is rare. These patients will manifest the clinical syndrome of hyperthyroidism with attendant systemic manifestations. The majority of these tumors are macroadenomas and may therefore be associated with mass effect. Biochemically, they demonstrate a nonsuppressed (inappropriately normal or increased) TSH level, in the setting of elevated thyroid hormones, that is, one does not see the feedback-inhibited TSH levels associated with primary hyperthyroidism. This syndrome needs to be distinguished from resistance to thyroid hormone which can lead to a similar hormone profile.

Endocrine Evaluation of a Pituitary “Incidentaloma”

With the widespread availability of MRI imaging, it is not uncommon for the radiologist to report the incidental finding of a pituitary mass. The endocrine evaluation requires screening of pituitary hormone levels to determine possible hypo- or hyperfunction, which will help to guide further therapy. Physiologic pituitary hypertrophy can be difficult to distinguish from a true pituitary adenoma, but requires an appreciation of the clinical setting to guard against unnecessary surgical intervention. Typically, adolescents, especially adolescent females, can demonstrate physiologic hypertrophy during puberty and for a few years thereafter, and women during pregnancy or during lactation can demonstrate physiologic enlargement of the gland from lactotroph hyperplasia. Patients with unrecognized severe primary hypothyroidism can present with pituitary enlargement, sometimes striking, as a result of thyrotroph hyperplasia, which resolves with appropriate thyroid replacement. Rarely, ectopic secretion of growth hormone releasing hormone or corticotropin releasing hormone may lead to somatotroph or corticotroph hyperplasia, respectively. All these conditions need to be distinguished from true pituitary adenomas.

NEUROLOGIC EVALUATION IN PITUITARY ADENOMAS

The primary neurologic manifestation of a pituitary mass is ophthalmologic, from compression of the optic nerves or chiasm traveling through the suprasellar cistern. Because the ipsilateral retinal ganglion cell axons cross in the optic chiasm en route to the contralateral occipital cortex, the pathognomonic finding on visual field examination is a bitemporal hemianopsia (“pie-in-the-sky”). The chiasm may sometimes be associated with a relatively short intracranial optic nerve segment (“prefixed”) or a relatively long intracranial optic nerve segment (“post fixed”). Depending upon the relative position of the tumor and chiasm, compression may also lead to uni- or bilateral optic nerve dysfunction, or compression of an optic tract, with a homonymous hemianopsia. Patients may sometimes report decreased acuity, although central vision is usually preserved unless compression is severe. A unilateral decrease in color vision is a sensitive sign of an early optic neuropathy, as is an afferent pupillary defect (Marcus Gunn pupil). This can be demonstrated by the “swinging flashlight test,” where light shown into the affected eye leads to a paradoxical increase in pupillary size, as the ipsilateral pupillo-constrictor fibers have been damaged by ipsilateral optic nerve compression and transmit relatively decreased retinal activity. Although pituitary adenomas will often invade the cavernous sinus and displace the cranial nerves within, cranial nerve dysfunction other than optic is uncommon. When present, and especially if of sudden onset, one should suspect a rapidly expanding mass, that is, pituitary apoplexy, or a more aggressive tumor, for example, a malignancy. Similarly, pituitary adenomas will often circumscribe but rarely constrict the cavernous carotid artery or cause neurovascular dysfunction;

when present an alternate pathologic diagnosis (especially meningioma) should be considered.

IMAGING OF PITUITARY ADENOMAS

Magnetic Resonance Imaging

MRI has revolutionized the visualization of intracranial lesions in general and pituitary tumors in particular. Useful pulse sequences for imaging the sella include T1 coronal and sagittal imaging before and after gadolinium administration. Other sequences (e.g., T2 coronal) may be useful, especially in the evaluation of cystic structures (fluid is generally hyperintense on T2) and previous hemorrhage (which may be dark on T2). Because of the relative decreased vascularity of adenomas as opposed to normal gland, timing of scanning relative to the administration of gadolinium is important; adenomas are generally focally hypointense to normal gland. Dynamic scanning using thin section gradient echo sequences may improve the sensitivity of visualization with small microadenomas (e.g., in Cushing disease), but gland heterogeneity may lead to decreased specificity.

Computerized Tomography

CT scanning has largely been supplanted by MRI, but remains useful in the delineation of bony anatomy for surgical planning and navigation. In those patients who cannot have an MRI, thin section coronal CT after contrast administration can be used to demonstrate a pituitary lesion. The presence of calcification on CT scanning can assist with the differential diagnosis, for example, a calcified cystic lesion, especially in a child, is highly likely to represent a craniopharyngioma.

MRI Characteristics

The normal gland enhances relatively homogeneously. It should be no greater than about 8 mm in coronal height in males and 10 mm in females. The infundibulum should be midline. The posterior pituitary may be bright on T1 without contrast (thought to represent secretory granules in axon terminals), although this is not a constant finding.

Pituitary adenomas should be focally hypointense relative to normal gland on T1 sequences after contrast. Microadenomas (<1 cm) may not significantly disrupt gland architecture. Macroadenomas (>1 cm) show upward bowing of the diaphragm sella associated with stalk deviation, and larger macroadenomas will demonstrate compression of the chiasm. The normal gland can be compressed, usually superiorly and posteriorly. The cavernous sinus is variably involved; it can be difficult to distinguish invasion as opposed to compression. Lesions surrounding the cavernous carotid are obviously invasive; lesions which circumscribe less than 25% are usually compressive. It has been suggested that lesions which circumscribe less than 67% of the carotid diameter are not invasive, but this is very variable. Adenomas can also be cystic, which may show T1 bright signal before contrast consistent with high protein fluid or hemorrhage.

Craniopharyngiomas may be cystic or solid, and intra- or suprasellar. Characteristics of the cyst fluid can vary with the protein content, with greater T1 hyperintensity associated with higher protein. The cyst wall is commonly calcified on CT, especially in children. Since the tumor is often suprasellar or arises along the stalk, the gland is typically compressed inferiorly from above.

Pituitary cysts can demonstrate variable imaging characteristics also depending upon their protein content. Rathke cleft cysts arise posteriorly in the sella, or sometimes along the stalk. They can be T1 hypo- or hyperintense depending on protein content, and can compress the gland anteriorly or from above. The cyst wall is usually thin with minimal enhancement. If there is a solid component or calcification, the diagnosis is more likely to represent a craniopharyngioma. Arachnoid cysts of the sella contain fluid isointense to CSF. There will be minimal if any enhancement of the wall, as the cyst is lined with a thin arachnoid layer. The gland is usually compressed inferiorly or anteriorly.

Other Sellar Lesions

Germinomas usually involve the posterior gland, stalk, and/or hypothalamus. They are typically brightly enhancing, and the borders are relatively indistinct. An enhancing lesion of the posterior sella associated with a pineal mass is highly likely to represent a germinoma. Germ cell tumors may disseminate along CSF pathways, leading to enhancement around the fourth ventricle. *Meningiomas* are usually brightly enhancing, often more so than the gland itself. As they arise from the dura, they can be variably located in and around the sella. If they arise from the diaphragm, they can be difficult to distinguish from

adenomas, but usually compress the gland from above. Meningiomas are often associated with a dural “tail,” which spreads out from the central mass of the tumor, and sometimes with focal hyperostosis. Meningiomas of the cavernous sinus can lead to carotid constriction, best seen on coronal images when comparing the transverse diameter of the intracavernous carotids, while adenomas rarely do. *Metastases* are typically locally invasive, brightly enhancing, and rapidly growing. They can spread hematogenously to the gland, or represent focal metastases to parasellar bony structures. When invading the cavernous sinus they can lead to a cavernous sinus syndrome, while adenomas rarely do.

SURGICAL TECHNIQUE

Although the first reported pituitary operation was a craniotomy done in 1889 by Sir Vincent Horsley,¹⁹ the first transsphenoidal approach was described in 1907 by Hermann Schloffer, a Viennese otolaryngologist, when he reached the sphenoid via a lateral rhinotomy incision.²⁰ Less disfiguring approaches were devised by the American neurosurgeon Harvey Cushing, who, with William Halsted, devised the sublabial approach in 1910, and another Viennese otolaryngologist, Oscar Hirsch, who described a fully endonasal procedure.²¹ Variants of these approaches remain in use today. Cushing performed over 200 transsphenoidal operations with an overall mortality rate of 5% – amazingly low given the lack of imaging, antibiotics, hormone replacement, and modern visualization – but decided in 1927 that the craniotomy was the more preferred procedure. With his decision, the transsphenoidal approach fell into relative disfavor, although kept alive by Dott in Edinburgh and Guiot in Paris, who introduced the use of intraoperative fluoroscopy as a navigation technique. When Jules Hardy of Montreal described the use of the operating microscope and reported the first removal of a pituitary microadenoma in 1962, pituitary surgery entered the modern era.²²

The transsphenoidal approach is relatively noninvasive, as it employs the nasopharynx and sphenoid sinus to access the skull base, but the surgeon is constrained to operate through a narrow corridor, to a relatively deep target, surrounded by important structures (carotids and optic apparatus). The surgeon must (1) approach and navigate to the tumor, (2) visualize the pathology, and (3) maximally resect the tumor while minimizing damage to the adjacent structures, that is, normal gland.

Approach

There are three transsphenoidal approaches to the sella in use today, in addition to the seldom necessary subfrontal craniotomy (Fig. 78-2). The sublabial approach, described by Cushing and Halsted, employs an incision in the gingiva with a submucosal dissection to the bony nasal aperture, and then a submucosal dissection along the septum to the sphenoid. Because the approach is not constrained by the width of the nares, the degree of access is relatively wide, but the gingival incision is painful, can be associated with numbness of the teeth and gums, and usually requires nasal packing to reapproximate the mucosa. The two endonasal approaches are constrained by the width of the nasal aperture, but avoid the complications associated with a gingival incision. The approach described by Hirsch uses a submucosal tunnel along the septum through an anterior mucosal incision immediately posterior to the columella; Hirsch felt that the submucosal tunnel gave him a relatively sterile field through which to access the sphenoid, important in the days prior to antibiotics, but this approach also requires nasal packing to reapproximate the mucosa to the septum, which patients find uncomfortable. The direct endonasal approach described by Griffith and Veerapen²³ and Cooke and Jones²⁴ uses either an incision at the insertion of the septum into the face of the sphenoid, or an enlargement of the natural ostia, with a posterior septectomy. Because there is no submucosal tunnel, nasal packing is usually not required.

Figure 78-2. Surgical approaches to the sella.

Navigation

It is critical to maintain accurate orientation in the sellar approach, as the face of sella is bounded immediately laterally by the carotid protuberances, and superolaterally by the optic canals. The insertion of the nasal septum posteriorly is usually a midline structure and can be used for orientation, while the sphenoid septations are very variable, and can be used for orientation only when correlated with preoperative imaging. Lateral intraoperative fluoroscopy as introduced by Guiot gives immediate real-time two-dimensional (2D) orientation in a sagittal plane, although it does not provide orientation in the coronal plane. Neuronavigational devices establish a three-dimensional (3D) reference plane by registering facial anatomy with preoperative imaging, and can be used to correlate intraoperative anatomy with preoperative imaging by means of a navigational “wand” recognized by the device in real time. This gives 3D information to guide the approach, but is dependent on the accuracy of the registration, and is less valuable in determining the adequacy of resection and orientation within the tumor, as tumor anatomy can change during resection. It is used routinely at many institutions, and is especially valuable in cases where normal bony anatomy has been destroyed by tumor growth or previous surgery.

VISUALIZATION

Hardy introduced the use of the intraoperative microscope to pituitary surgery and it remains in widespread use today. After the introduction of the rigid endoscope to field of sinus surgery by otolaryngologists, its use in transsphenoidal surgery was reported by Janowski in 1992²⁵; it has now been the topic of multiple reviews and has become widely accepted. Advantages of the microscopic approach are the superb optics and binocular vision; a major disadvantage is the requirements for direct line-of-sight viewing, though for smaller tumors, that is, the microadenomas of Cushing disease, this disadvantage may not be significant. The endoscope gives a wider field of view and has the ability to see at angles off the primary visual axis. However, most endoscopes offer only monocular vision with no depth of field, though 3D endoscopes are under development. Although the endoscopic technique has been touted as “less invasive,” the need to supply sufficient access for both the endoscope and working instruments may actually require greater dissection of the sphenoid, ethmoids, and possibly resection of the turbinate(s). A number of meta-analyses have been published comparing the two techniques, usually using recent endoscopic results compared to older historical microscopic series. The overall results for secretory tumors, where there are defined biochemical criteria for remission, appear similar, with a possible edge to endoscopy in larger secretory tumors in association with perhaps a small increased risk of vascular complications.

Figure 78-3. A: The coronal view (T1-weighted image with contrast) of a large nonfunctioning macroadenoma with significant chiasm compression. B: The intraoperative MRI (T1-weighted image with contrast) shows tumor removal with fat packing and hemostatic material in place. The chiasm is decompressed. C: The postoperative MRI at 8 weeks shows partial resorption of the fat packing and hemostatic material.

Determining the Adequacy of Resection

As most pituitary tumors are removed by internal decompression allowing collapse of the tumor capsule, there may be no direct visualization of the adequacy of resection. Endoscopic inspection of the tumor capsule can sometimes provide an indication, but prolapse of the diaphragm as the capsule collapses (itself an indication of adequacy of decompression) can make thorough internal visualization difficult. Intraoperative MRI (iMRI) imaging has proven useful in the determination of resection

adequacy, as the technique allows the surgeon to visualize areas of residual tumor not seen with direct inspection. A comparison of preoperative, intraoperative, and postoperative imaging in a patient with a large nonfunctioning macroadenoma is shown in [Figure 78-3](#). A number of studies have reviewed the utility of intraoperative imaging. Most report that additional tumor resection can be achieved in about 20% of cases, but this is partly a function of when, during the course of the procedure, the surgeon chooses to image, and premature imaging may bias the results in favor of demonstrating the utility of the iMRI.²⁶ In addition, imaging can show whether the chiasm has been adequately decompressed, which correlates with postoperative visual improvement, and may assist in the avoidance of postoperative complications. The iMRI equipment is costly, however, and requires significant alterations in surgical workflow and operative time, with the risk of operating in close proximity to a high-strength magnetic field. It has been debated whether resection can be better optimized with the use of the iMRI versus the endoscope, and each approach has its adherents. In those few studies combining the use of endoscopy with the iMRI, most showed that some degree of additional resection can be achieved after imaging.^{27,28}

Surgical Technique

7 There are a number of variations in surgical technique, determined by the preference of the surgeon and the dictates of the anatomy. The patient is given preoperative broad-spectrum antibiotic coverage and stress-dose steroids (except for patients with Cushing disease, where preoperative steroid coverage can be held). After the induction of general endotracheal anesthesia, the patient is positioned in a semirecumbent position. The head may be turned toward the surgeon or in a neutral position if two surgeons will together be performing an endoscopic approach. The head can be held in a gel headrest or pinned using the Mayfield clamp. If neuronavigation is used, the reference fiducials are affixed and registered, or the lateral fluoroscope is positioned. The area of the proposed incision is infiltrated with local anesthesia with epinephrine as a vasoconstrictor. With a direct endonasal approach the incision is made along the posterior septum, and either the septum is fractured and deviated contralaterally, or a posterior septectomy is performed. With a microscopic approach, a nasal speculum is introduced, compressing the turbinates laterally. With the endoscopic approach, the middle turbinate may require removal to increase access. The face of the sphenoid is opened, and any septations impeding access are removed. Anatomy of the sphenoid septations gleaned from preoperative imaging can be useful in guiding the approach to the midline sella, which is drilled to dura. The dura is lightly cauterized and incised. For macroadenomas, the tumor is usually immediately evident, and can be removed with ring curettes back to normal gland. With microadenomas, especially those causing Cushing disease, detection can be difficult. The gland is hemisected into quadrants, with biopsies taken from each quadrant guided by the preoperative IPSS lateralization. If no tumor is found on frozen section analysis, a hemihypophysectomy can be performed. It is important to preserve normal gland; this can usually be distinguished by color and consistency, and, in macroadenomas, is usually compressed posteriorly and superiorly. As the resection proceeds, the diaphragm should prolapse into the field in cases of preoperative chiasm compression. After tumor removal, the resection cavity is inspected for residual tumor; 30-degree or 70-degree endoscopes are useful in visualizing areas not in direct line-of-sight. Hemostasis is achieved by packing with any number of available hemostatic materials. After hemostasis, most surgeons pack the tumor cavity with fat, muscle or absorbable hemostatic material; a water-tight seal is especially important if a CSF leak has been created. The fat is buttressed in place and the sellar floor reconstructed with septal cartilage or bone, titanium mesh, or proprietary plastic materials. Fibrin glue or other sellar sealant can be used if needed. The septum is returned to the midline. With a direct endonasal approach, nasal packing is usually not required. If a submucosal tunnel was created during the approach, nasal packing is placed; if a sublabial incision was used, the gingival mucosa is closed with a few absorbable sutures. The use of iMRI can be timed at the discretion of the surgeon. Some surgeons will maintain the sterile field and image before closure; others complete the closure (since reopening is usually straightforward) and image prior to anesthesia reversal.

Postoperative Management

Careful monitoring in the postoperative period is essential. Most patients require only one to two nights of hospitalization; an ICU stay is usually not necessary. Potential complications include postoperative hemorrhage, CSF leakage, meningitis, epistaxis, and endocrine dysfunction.

1. Postoperative hemorrhage can occur into the tumor resection cavity with resulting visual

compromise, thus frequent testing of postoperative acuity and confrontation fields is necessary. Immediate reexploration may be required.

2. CSF leakage can be sometimes difficult to detect, as postoperative nasal drainage is common. If suspected, the best confirmatory test is to assay the collected fluid for tau protein (beta transferrin), which is found in CSF but not in nasal secretions or blood. If positive, treatment options include the insertion of a lumbar drain to lower CSF pressure for a few days and allow spontaneous closure of the leak, but oftentimes the optimal course is reexploration and repacking of the tumor bed with closure of the fistula.
3. Infection in the immediate postoperative period is rare. Prophylactic antibiotic coverage is maintained for 24 hours, or until the nasal packing is removed. Delayed fever, especially with signs of meningitis, requires evaluation with a lumbar puncture; an occult CSF leak should be suspected. Patients may be at increased risk of sinus infection for many months.
4. Bloody nasal secretions are common, and usually clear with nasal irrigation. Frank epistaxis is rare, usually occurs 2 or 3 weeks after surgery, and is most often caused by delayed hemorrhage from a septal branch of the sphenopalatine artery. It can sometimes be managed with nasal packing, but may require cauterization or clipping, or rarely embolization.
5. Endocrine management. Postoperative endocrine management is best done in conjunction with an endocrinologist. Monitoring for pituitary insufficiency, especially hypoadrenalism, is necessary. Some centers prophylactically treat with replacement steroids until adequate cortisol levels can be proven; early discharge (on POD #1 or #2) may require outpatient steroid supplementation until testing can be completed. Others monitor for adrenal insufficiency without replacement, though this is safest as an inpatient. After successful surgery for Cushing disease, immediate and prolonged (6 to 12 months) hypoadrenalism is expected if remission is achieved. Postoperative steroid replacement will be required until normalization of the pituitary–adrenal axis is documented. Complete postoperative hormone testing is usually performed at 6 to 8 weeks in order to establish the presence of remission of hormone excess and reassess the patient's pituitary function, including the possible development of new pituitary hormone deficiencies (occurring in 5% to 10% of patients). Conversely, pre-existing pituitary hormone deficiencies may resolve in 30% to 40% of patients postoperatively. Transient diabetes insipidus is not uncommon (about 10% to 20% of cases), but permanent DI is unlikely (approximately 1% to 2%). It is important to monitor urine output, urine-specific gravity, and serum sodium levels in the immediate postoperative period, and treat with desmopressin (vasopressin analog devoid of pressor activity) if needed. Mild cases can be treated with *ad lib* fluid intake if the patient's thirst mechanism is intact, as it usually resolves spontaneously within a few days. Sodium levels should be monitored intermittently as an outpatient for 10 to 14 days, as SIADH can develop in a delayed fashion, and a triphasic pattern (DI → SIADH → DI) has been described. Patients with SIADH who are symptomatic from hyponatremia may present with headaches and nausea, and neurologic dysfunction – confusion and rarely seizures – can occur if the hyponatremia is severe (serum sodium < 120 to 125 mEq/L). Mild SIADH usually responds to fluid restriction and salt supplements; symptomatic patients may require 3% hypertonic saline. It is important not to correct the hyponatremia too quickly, as central pontine myelinolysis can occur.

RESULTS AND COMPLICATIONS

Reviews of the literature on the outcome after transsphenoidal surgery require recognition of a number of factors potentially affecting the interpretation of the results. Endocrine diagnostic techniques, biochemical criteria for remission for secretory tumors, and surgical techniques have changed over the years, which can make comparison difficult. There may be a publication bias favoring newer approaches over old. Meta-analyses can be useful, but need to be interpreted with an eye to the underlying data, and most of the meta-analyses review retrospective case series rather than randomized studies. A recent meta-analysis reviewed short-term remission and recurrence data over the past 25 years and reported overall short-term surgical remission rates of 61.7% in prolactinomas, 44.4% in nonfunctioning tumors, 60.9% in acromegaly, and 72.7% in Cushing disease, with no clear-cut improvement over the interval. Because of the historical time frame, the majority of the series used the microscopic approach. The risk of recurrence per patient year at risk was reported to be 3.4% for prolactinomas, 2.2% for nonfunctioning tumors, 0.7% for acromegaly, and 2.3% for Cushing disease.²⁹

Much of the recent literature describes the results with endoscopic approaches, often in comparison to historical microscopic results; no major randomized comparison has been published. One recent review

included nine pooled studies; they reported a 78% rate of gross tumor removal (GTR), 81% remission rate in Cushing disease, 84% remission in acromegaly, and 82% in prolactinomas, with a 2% incidence of CSF leak and 1% incidence of permanent DI. There were two deaths (0.24%), both from vascular injury.³⁰ This review was overweighted by a single large study which contributed 39% of the secretory cases. An additional 12 endoscopic studies were included in a second meta-analysis, with an overall rate of GTR 68%; 72% remission in acromegaly, 75% remission in Cushing disease, and 78% remission in prolactinomas.³¹ Meta-analyses comparing the microscopic and endoscopic approaches now exist, often using the same underlying data but reaching differing conclusions. Three of these are summarized in [Table 78-5](#); one of the three shows a resection benefit with endoscopy, while two do not. In addition, a number of reviews have specifically analyzed complication rates between endoscopic and microscopic techniques.^{32–34} Three of these reviews report that, in comparison to a retrospective analysis of traditional sublabial approaches, the endoscopic approach appears to show decreased operating time, length of hospital stay, risk of diabetes insipidus, nasal complications, and patient pain and discomfort. The largest study incorporated 38 studies with greater than 10 patients; a total of 5,643 patients were included.³⁵ This study found no significant difference in the incidence of complications with the exception of a statistically significant increased risk of vascular complications with endoscopic procedures, perhaps due to the wider exposure possible within the endoscope. The overall incidence of typical complications for both endoscopic and microscopic procedures is summarized in [Table 78-6](#), abstracted from this review.

Table 78-5 Comparison of Endoscopic and Microscopic Approaches

Meta-Analysis	Studies Reviewed (Patients)	GTR ^a	Complication Differences	Hospital Stay
Gao et al. ³⁶	15(1,014)	71% endo; 58% micro (<i>p</i> = 0.0001)	Increased risk of septal perforation with micro (<i>p</i> = 0.01)	Shorter with endo
Ammirati et al. ³⁵	38(5,643)	69% endo; 64% micro (NS)	Increased risk of vascular complications with endo (<i>p</i> <0.0001)	NA
Goudakos et al. ³²	11(806)	66% endo; 60% micro (NS)	DI less frequent with endo (<i>p</i> = 0.003)	Shorter with endo

^aGTR defined as radiographic for nonfunctioning adenomas (NFA) or biochemical remission for secretory tumors.

Table 78-6 Comparison of Complication Rates in Endoscopic Versus Microscopic Surgery Based on a Meta-Analysis of 38 Studies³⁵

Complications/Events	Endoscopy Studies	Proportion (95% CI)	Microscopy Studies	Proportion (95% CI)
Death	19	0.49% (0.23–0.84%)	18	0.23% (0.10–0.42%)
CSF leak	24	7% (4.84–9.52%)	19	6.34% (3.86–9.37%)
Meningitis	13	1.11% (0.642–1.71%)	14	2.08% (0.83–3.86%)
Vascular complications ^a	17	1.58% (1.07–2.19%)	12	0.5% (0.28–0.78%)
Visual loss	13	0.72% (0.37–1.19%)	14	0.60% (0.23–1.14%)
Diabetes insipidus temporary	18	9.1% (6.57–11.99%)	14	10.23% (6.5–14.69%)
Diabetes insipidus permanent	21	2.31% (1.41–3.41%)	15	4.25% (1.96–7.36%)
Hypopituitarism	17	8.51% (5.16–12.59%)	12	11.64% (5.14–20.32%)
Complete resection	22	68.77% (64.37–73%)	18	64.44% (57.62–70.98%)

Prolactinomas

Given the efficacy of dopamine agonist treatment, surgery for prolactinomas is rarely indicated. Nonetheless, it remains effective in selected cases, especially in smaller tumors. A large surgical series reported initial remission of 91.3% in microadenomas, with a recurrence rate of 7.1%. The overall remission rate was 53.2% including giant prolactinomas.³⁷

Acromegaly

Surgery remains the most effective treatment for acromegaly, despite the availability of medical therapy. Multiple surgical series in the literature report remission rates on the order of 50% to 65% for macroadenomas, and 70% to 90% for microadenomas ([Table 78-7](#)). Results from specialized centers are

generally better than those results reported from tumor registries.

Cushing Disease

Surgical results for Cushing disease are summarized in Table 78-8. Remission rates for microadenomas are generally from 70% to 90%. In those patients not in remission after the initial procedure, a second exploration is sometimes recommended, which can achieve remission in an additional 50% to 70% of patients.^{46,47} While early as opposed to late reoperation is technically less challenging, delayed remissions have been reported, and it is important to determine that postoperative levels have plateaued at an elevated level before proceeding with reexploration.⁴⁸

MANAGEMENT OF PITUITARY ADENOMAS BY SYNDROME

With the advent of medical therapy for some of the secretory tumors, surgical indications have changed, and surgical decision making needs to be considered in the context of the available treatment options.

Prolactinomas

8 Medical treatment with dopamine agonists (DAs) is considered first-line therapy for most patients with prolactinomas even those with large and invasive tumors.⁵⁴ Not all patients require treatment – patients with asymptomatic, stable microadenomas, who are not pursuing fertility, can often be followed expectantly. The commonly used agents – bromocriptine and cabergoline – are both oral agents with excellent efficacy, minimal side effects (usually GI disturbances, although cognitive issues and psychological effects have been reported, including depression, anxiety, and impulsivity), and are relatively inexpensive. Cabergoline is more effective and generally better tolerated than bromocriptine.

High doses of cabergoline (> 3 mg/d) have been associated with cardiac valvular dysfunction, but this does not appear to be a significant risk in the dose range usually prescribed for prolactinomas (typically 0.5–2.0 mg/wk, [Table 78-9](#)). Because they act as metabolic inhibitors and are not cytotoxic, lifelong therapy is usually required, although there are some reports of apparently long-term remission after discontinuation of the drugs.⁵⁵ The tumor shrinkage in response to these agents is often dramatic. Surgical treatment is indicated after the failure of medical therapy, intolerance to the medications, and in cases where the patient prefers the possibility of surgical remission to life-long medical treatment. Other indications for surgery include cerebrospinal fluid leak, occurring as a result of shrinkage of large, invasive prolactinomas in response to medical therapy, and pituitary apoplexy, which may rarely complicate use of dopamine agonists. Relative indications include cystic tumors, which may not shrink with medical treatment, and in infertile women who wish to become pregnant without medication. Long-standing visual dysfunction will often improve after tumor shrinkage from medical treatment, while rapidly progressive visual loss, especially associated with hemorrhage, mandates surgical removal. Radiation therapy can be recommended for tumors unresponsive to medical and surgical treatment. Temozolomide, an orally active alkylating agent, has been administered (“off label”) to some patients with aggressive pituitary adenomas or carcinomas (including, but not limited to, aggressive or malignant prolactinomas), and may transiently achieve tumor control.

Acromegaly

9 Surgery remains first-line treatment in most cases, though some would argue for primary medical treatment in those cases unlikely to be surgically cured, or in patients who are not optimal surgical candidates.⁵⁶ The available medical treatments include somatostatin analogs (SSAs), dopamine agonists, and growth hormone receptor antagonists. Each treatment modality has its own relative advantages and disadvantages. Surgery is rapidly effective in lowering GH levels, leads to immediate relief of symptoms from mass effect (visual loss), and has the potential to be curative, depending upon the size and degree of tumor invasiveness. Cabergoline, the most potent dopamine agonist, is sometimes effective in acromegaly (leading to endocrine remission in 20% to 30% of cases), but usually only when the IGF1 level is minimally elevated ([Table 78-10](#)). However, it is an oral agent with minimal risk and relatively inexpensive. Its use in acromegaly is not FDA approved. The SSAs – octreotide and lanreotide – are effective in normalizing IGF1 in about 40% to 50% of patients previously selected for responsiveness to SSAs, though recent studies in unselected de novo patients report effectiveness in only 20% to 25%. They lead to tumor shrinkage to some degree also in about 40% to 50% of cases, though the shrinkage seen is usually not dramatic (unlike the shrinkage seen in prolactinomas with DAs). They are both injectable agents, given every 4 weeks in their long-acting forms, and usually well tolerated; the most common side effects are GI disturbances and occasionally cholelithiasis and hyperglycemia. Both agents are expensive. A recent study compared the use of octreotide and pasireotide in acromegaly; in de novo patients (no previous surgery) remission was achieved in 26% with pasireotide and 17% with octreotide.⁵⁷ The growth hormone receptor pegvisomant blocks the peripheral action of growth hormone and leads to dramatic lowering of the IGF1 level in up to 95% of patients, but has no direct antitumoral effect. Because of this, it is best used in combination with the SSAs in cases of incomplete response, or to control the IGF1 while awaiting the beneficial effects of radiation treatment. Arguments have been made for both pretreatment of surgical cases with SSAs, and debulking of unresectable tumors prior to medical therapy. In three randomized studies, pretreatment was shown to improve postoperative remission rates, but the control remission rate in these studies was lower than would be expected from comparisons to the literature. In a recent meta-analysis, a borderline positive affect with pretreatment was detected in 10 studies, both randomized and retrospective, which did not reach statistical significance, while the analysis of the prospective controlled trials (with historically low pretreatment remission rates) was statistically significant in showing benefit.⁵⁸ Pretreatment in symptomatic acromegalic patients can, however, improve anesthetic risk by improving attendant comorbidities, especially cardiomyopathy and airway management, and for this reason alone is sometimes worthy of consideration.⁵⁹ The indications for debulking an unresectable tumor have been debated; since SSA treatment appears to be more effective with lower IGF1 levels,⁶⁰ an argument can be made for removing as much tumor as possible and treating the remainder with medication. In cases where primary medical treatment was unsuccessful, surgical debulking has been shown to improve remission, even if surgical “cure” cannot be achieved.⁶¹ Radiation therapy is usually a third-line option for patients who are not in remission after surgery and do not respond or tolerate medical therapy. A flowchart for the management of acromegaly is shown in [Algorithm 78-1](#).

Table 78-9 Medications Used to Treat Prolactin-Secreting Pituitary Adenomas

Name	Mechanism of Action	Usual Dose Range	Adverse Effects
Bromocriptine	Dopamine receptor agonist	1.25–10 mg by mouth daily (in divided doses)	Nausea, vomiting, dizziness, headache, nasal congestion, constipation, digital vasospasm, vivid dreams, anxiety, depression, impulsivity
Cabergoline	Dopamine receptor (D2 selective) agonist	0.5–2.0 mg by mouth weekly (in a single or divided doses)	Same as bromocriptine (often better tolerated by patients); high doses (>3 mg/d) have been associated with cardiac valvulopathy

Table 78-10 Medications Used to Treat Acromegaly

Name	Mechanism of Action	Usual Dose Range	Adverse Effects
Octreotide acetate	Somatostatin receptor agonist (sstr2 and sstr5)	100–500 mcg subcutaneously every 8 hrs	Gastrointestinal side effects, cholelithiasis, hyperglycemia, hypoglycemia, vitamin B12 deficiency, hypothyroidism, bradycardia, hair loss
Octreotide LAR	Somatostatin receptor agonist (sstr2 and sstr5)	10–40 mg intramuscularly every 4 wks	Same as octreotide acetate
Lanreotide depot	Somatostatin receptor agonist (sstr2 and sstr5)	60–120 mg deep subcutaneously every 4 wks	Same as octreotide acetate
Cabergoline ^a	Dopamine receptor (D2 selective) agonist	0.5–7.0 mg by mouth weekly	Nausea, vomiting, dizziness, headache, nasal congestion, constipation, digital vasospasm, vivid dreams, anxiety, depression, impulsivity; high doses (>3 mg/d) have been associated with cardiac valvulopathy
Pegvisomant	Growth hormone receptor antagonist	5–40 mg subcutaneously daily	Lipohypertrophy, skin rash, hepatotoxicity

^aCabergoline is not approved by the FDA for use in acromegaly.

**Algorithm 78-1.** Treatment algorithm for acromegaly.**Table 78-11 Medications Used to Treat Cushing Disease**

Name	Mechanism of Action	Usual Dose Range	Adverse Effects
Ketoconazole	Adrenal steroidogenesis inhibitor	200–600 mg by mouth two to three times daily	Nausea, dyspepsia, skin rash, hepatotoxicity, hypogonadism, gynecomastia
Metyrapone	Adrenal steroidogenesis inhibitor	250–1,000 mg by mouth four times daily	Nausea, dizziness, hirsutism, hypertension, edema, hypokalemia
Mitotane	Adrenal steroidogenesis inhibitor	0.5–3.0 g by mouth three times daily	Nausea, diarrhea, dizziness, ataxia, confusion, hepatotoxicity, rash, gynecomastia, dyslipidemia, teratogenicity
Etomidate	Adrenal steroidogenesis inhibitor	0.03 mg/kg intravenously as a bolus, followed by infusion: 0.1–0.3 mg/kg/hr	Sedation
Cabergoline	Dopamine receptor (D2 selective) agonist	0.5–7.0 mg by mouth weekly	Nausea, vomiting, dizziness, headache, nasal congestion, constipation, digital vasospasm, vivid dreams, anxiety, depression, impulsivity; high doses (>3 mg/d) have been associated with cardiac valvulopathy
Pasireotide ^a	Somatostatin receptor agonist (sstr1, 2, 3, and 5)	0.3–0.9 mg subcutaneously twice daily	Gastrointestinal side effects, cholelithiasis, hyperglycemia (more often than other somatostatin analogs), vitamin B12 deficiency, hypothyroidism, bradycardia, hair loss
Mifepristone ^a	Glucocorticoid receptor antagonist	300–1,200 mg by mouth daily	Fatigue, headache, nausea, hypokalemia, vaginal bleeding, endometrial thickening, pregnancy termination, abnormal thyroid function tests, dyslipidemia

^aOnly pasireotide and mifepristone are approved by the FDA for use in Cushing disease.

Cushing Disease

Surgical excision is generally considered to be first-line treatment; if unsuccessful, early reexploration has been recommended with some additional degree of success.⁴⁶ Surgical remission leads to immediate lowering of ACTH levels and cortisol production, and steroid replacement is required as the normal gland will remain suppressed for months. If transsphenoidal surgery is unsuccessful, a number of treatment options are available. Medical therapy can control hypercortisolemia by inhibition of cortisol production by the adrenal glands (ketoconazole,⁶² metyrapone, mitotane, etomidate), at the level of the pituitary tumor by acting on somatostatin receptors (pasireotide)⁶³ or dopamine receptors (cabergoline),⁶⁴ or by cortisol receptor blockade (mifepristone),⁶⁵ and combination therapy has been suggested as well.⁶⁶ Medications are most commonly used in patients who have persistent hypercortisolism after pituitary surgery and are not candidates for additional surgery. Each medication has its attendant set of side effects, including liver function abnormalities with ketoconazole, hyperglycemia with pasireotide, GI disturbances with high-dose cabergoline, and hypokalemia and endometrial thickening with mifepristone; none represents optimal therapy but each may offer advantages in the individual patient (Table 78-11). Only pasireotide and mifepristone are FDA approved for use in patients with Cushing disease. Bilateral adrenalectomy remains a viable option, with immediate resolution of hypercortisolemia, but requires lifelong mineralocorticoid and glucocorticoid replacement. It is associated with radiographic progression of the pituitary adenoma in about half the cases, and a smaller number of patients may develop Nelson syndrome.⁶⁷ Radiosurgery with interim medical control is often a reasonable option after unsuccessful surgery; normalization of cortisol levels occurs in about 50% to 70% of patients within 2 years of treatment, but with a significant risk of anterior hypopituitarism.^{68,69} A flowchart for the management of Cushing disease is shown in Algorithm 78-2. Recurrent Cushing disease after initially successful surgery remains a significant problem. Reported recurrence rates are approximately 2% per year,²⁹ but some series report an overall incidence of as high as 25%.⁷⁰ Reexploration for recurrence is a reasonable option with success rates on the order of 50%; but the alternative therapies described above merit consideration as well.^{71,72}

Nonfunctioning Tumors

Surgical removal remains as first-line treatment; there are no good medical options (as the response to dopamine agonists or SSAs has been poor). Small nonfunctioning tumors (<1 cm) can be followed with serial imaging, but macroadenomas should usually be resected, especially those which are close to the chiasm or enlarging on serial scans, even without visual abnormalities. After subtotal resection it is in many cases reasonable to follow the residual tumor, with reoperation or radiation therapy reserved for those which later enlarge. Guidelines for the management of pituitary incidentalomas have been recently published.⁷³

Thyrotropin-Secreting Pituitary Adenomas

Pituitary surgery is first-line therapy in most cases. Patients with hyperthyroidism can be pretreated with SSAs or methimazole in order to control hyperthyroidism preoperatively, if present. After surgery, patients with residual tumors or persistent hyperthyroidism may benefit from SSA therapy, which is very effective in controlling hyperthyroidism and also affords some degree of tumor control. Radiation therapy is an alternative option in patients who are not in remission after pituitary surgery.

SOCIOECONOMIC CONSIDERATIONS

10 A number of socioeconomic considerations now affect the practice of pituitary surgery. The volume-outcome relationship, which has been shown to be manifest in a number of surgical subspecialties, holds true here as well. This was originally suggested by a study showing improved outcomes for acromegaly with a dedicated pituitary surgeon.⁷⁴ Further studies have demonstrated a decrease in complication rate with increased experience,⁷⁵ and a significant decrease in operative mortality after pituitary surgery in high-volume as opposed to low-volume centers.⁷⁶ With the multiplicity of available treatment modalities, comparative cost-benefit analyses are now being performed. Treatment algorithms in acromegaly which incorporated transsphenoidal surgery were shown to be less expensive than those using medical therapy alone, and algorithms using primary surgery followed by adjunctive medical treatment as opposed to the converse approach were shown to be 30% less costly overall.⁷⁷ In Cushing disease, the economic burden of managing patient comorbidities was shown to significantly decrease after successful surgery.⁷⁸ Despite the introduction of new pharmacologic agents, it is likely that surgery will continue to play a major role in the treatment of pituitary disorders; given the multiplicity of options, however, care is best individualized for a given patient in a multidisciplinary setting.

SECTION L: LUNG

Chapter 79

Lung Neoplasms

Andrew C. Chang and Jules Lin

Key Points

- 1 Lung cancer remains the leading cause of cancer-related death in the United States.
 - 2 Advances in molecular biology including genomic and proteomic techniques constitute promising methodologies for the diagnosis and patient-tailored management of non-small cell lung cancer (NSCLC), but to-date these strategies have not been validated for broad clinical implementation.
 - 3 Low-dose screening chest CT can reduce lung cancer-related mortality in “at-risk” patients.
 - 4 Common sites of distant metastases are bone, liver, adrenal glands and the central nervous system; therefore, the metastatic evaluation includes a PET scan and CT of the chest and upper abdomen, and a brain MRI.
 - 5 Resection remains the mainstay in the treatment of lung cancer, yet only about 20% of all patients diagnosed with lung cancer are considered resectable (stages I to IIIA). VATS/robotic approaches have changed the landscape for operation although the principles of oncologic resection remain unchanged.
 - 6 In addition to new chemotherapeutic agents, new radiation techniques, such as hyperfractionated or accelerated schedules, also merit further exploration in neoadjuvant trials with concurrent chemotherapy.
 - 7 Taken as a whole, neoadjuvant therapy trials have demonstrated the feasibility of induction chemotherapy and radiation followed by resection for the treatment of selected stage IIIA NSCLC. Most studies show improved rates of resectability and survival in comparison with the historical experience for surgical resection or radiation alone.
 - 8 Generally, a solitary lesion is more likely to be a metastasis if the primary tumor was a sarcoma or a melanoma. If the primary tumor originated in the head, neck, or breast, it is more likely to be a new primary lung cancer.
-

INTRODUCTION

1 Although population estimates of both the incidence and mortality of lung cancer have begun to decline, lung cancer remains second only to heart disease among all causes of mortality. With 224,210 new cases and 159,260 deaths projected for 2014, lung cancer is the leading cause of cancer-related death in the United States. Lung cancer is second in cancer prevalence only to prostate cancer among men and breast cancer among women, and remains the leading cause of cancer-related death for both sexes. Since 2005, both the annual incidence and mortality rates due to lung cancer have started to decrease in the United States, reflecting improvements in cancer control and prevention, particularly efforts to reduce the prevalence of smoking.¹ There is also significant regional variation in both lung cancer incidence and mortality. Among men, lung cancer mortality has decreased from 1996 through 2005 in over 80% of the 50 states and the District of Columbia, whereas among women over the same period, mortality decreased in only three states (California, New Jersey, and Texas) and has increased in 13 other states, primarily in the Midwest and South,² although more recently consistent rates of decline have been noted for both men and women.

The best predictor of survival for patients with lung cancer is still tumor stage. Resection remains the mainstay in the treatment of lung cancer, yet only approximately 37% of all patients diagnosed with lung cancer are considered resectable (with either local or regional disease, that is, stages I to IIIA). Even among patients who have undergone complete resection with curative intent for early-stage disease, as determined using pathologic Tumor–Node–Metastasis (TNM) criteria, a substantial number will have recurrence of their cancer.³

Clinical trials continue to demonstrate that adjuvant chemotherapy can improve survival over surgery alone for early-stage lung cancer.⁴⁻⁶ Importantly, screening low-dose chest computed tomography (CT) appears to improve early detection of resectable lung cancer, with an improvement in overall survival,^{7,8} albeit with a possible risk of overdiagnosis.⁹ As understanding of the molecular changes occurring in lung cancer evolves, new strategies that allow for early detection and classification of lung cancer will provide valuable information for the treatment of patients.

HISTORY

Ferdinand Sauerbruch, whose interests included the physiology of pneumothorax and is considered one of the pioneers of thoracic surgery, reported the first successful lobectomy for lung carcinoma in 1920. At that time, it was believed that only total pneumonectomy would provide a cure for lung cancer. Dr. Evarts A. Graham performed the first successful single-stage pneumonectomy for a left upper lobe bronchogenic carcinoma in 1933,¹⁰ although this was neither the first pulmonary resection nor pneumonectomy, establishing the modern era of thoracic surgery for lung cancer. Ultimately, Dr. Graham succumbed to lung cancer himself in 1957, and was outlived by his patient, Dr. James L. Gilmore, who had continued to smoke.¹¹

EPIDEMIOLOGY

Recently, population studies have demonstrated sustained declines in lung cancer incidence among both men (80.0 cases per 100,000), and women (55.1 per 100,000) as of 2010. African-American men continue to have the greatest incidence of lung cancer, in excess of nearly 20% (94.7 per 100,000) over the cases reported for all men.^{12,13} The decline in incidence as well as mortality may be due in part to public health efforts to promote smoking cessation.¹⁴ In a follow-up to the Seven Countries Study of smoking-related mortality, follow-up analysis of the initial cohorts studied from Europe, the United States and Japan confirmed that cigarette smoking increased the risk for death due to lung cancer with a hazard ratio of 4.2 per pack of cigarettes smoked. Furthermore, the death rates due to lung cancer decreased to that of never-smokers after 10 years of smoking cessation.¹⁵ Exposure to environmental “second-hand” cigarette smoke or other particulate matter air pollution can also contribute to an increased risk of lung cancer,^{16,17} particularly adenocarcinoma.^{17,18}

PATHOLOGIC CLASSIFICATION

Uniform classification of lung cancer is important both to provide consistent treatment for patients and to allow standardization in reports of epidemiologic, clinical, and basic scientific studies. Currently, the classification is largely histologic and is based on light microscopy findings determined from specimens obtained by resection or needle biopsy, permitting its wide application by surgical pathology laboratories where more advanced techniques might not be readily available. Nevertheless, immunohistochemical and electron microscopy analyses are important, particularly in the diagnosis of neuroendocrine tumors, or for distinguishing between primary bronchogenic adenocarcinoma and metastatic lesions. The most recent revision of the World Health Organization (WHO) classification (Table 79-79) was published in 2004¹⁹ but is largely unchanged from the previous revision in 1999.²⁰ Guidelines for defining preinvasive lesions such as squamous dysplasia and carcinoma in situ are provided. Recognition and definition of the heterogeneity among adenocarcinomas is reflected in the subclassification of this group, including more restrictive definitions for bronchioloalveolar carcinoma (BAC), which has been redesignated as “adenocarcinoma in situ.”^{20a} Definitions for the spectrum of neuroendocrine tumors, ranging from typical and atypical carcinoid, to small cell lung cancer (SCLC) and large cell neuroendocrine carcinomas are provided.

TUMOR BIOLOGY

Genetic alterations in several regulatory pathways including apoptosis, cell cycle and mitogenic signaling have been identified in tumors of patients with non-small cell lung cancer (NSCLC). Chromosomal loss of heterozygosity (LOH) or allelic gain appears to occur more frequently among

patients with adenocarcinoma and history of tobacco exposure than among patients without any smoking history. Mutations among the *Ras* oncogenes, particularly *K-ras*, are characterized by the accumulation of DNA adducts within these genes, predominantly among patients with a history of tobacco use.²¹ This has been attributed to the exposure to tobacco carcinogens such as benzo[a]pyrene (BaP), its activated form, benzo[a]pyrene diol epoxide (BPDE), and N-nitrosamines. These genes encode GTP-binding proteins which participate in cellular signal transduction; their mutation results in constant Ras activation. Another family of oncogenes, *Myc*, encoding several transcription factors, is activated by gene amplification, primarily in SCLC.²¹

The tumor suppressor gene, *p53*, is the most frequently mutated gene in human cancer. Among patients with a history of tobacco use, mutations within *p53* were identified in over 50% of patients with NSCLC, particularly squamous cell carcinoma (SCC) and non-AIS adenocarcinoma.^{22,23} Among patients with stage I tumors, those with mutations, particularly truncating, structural, or those that abolished DNA binding, demonstrated significantly worse actuarial survival in comparison with patients who had wild-type *p53*. In contrast those patients with missense mutations did not demonstrate significantly different survival than those with wild-type *p53*. In several clinical trials demonstrating the benefit of adjuvant chemotherapy among patients with resected NSCLC, the presence of *p53* mutations was not associated with any significant survival difference among patients assigned to treatment or observation arms.^{24,25} Among patients found to have mutations in the *p53* gene, those treated with adjuvant chemotherapy had worse outcomes than untreated patients.²⁵ Investigators have also identified *p53* protein expression, determined by immunohistochemical analysis, as a predictor of poor outcome in patients with stage I NSCLC.²⁶ Furthermore, *p53* expression is associated with tumors more likely to demonstrate distant metastases.²⁷ Notably, patients with *p53* expression detectable by immunohistochemistry appear to have improved survival following adjuvant chemotherapy compared to patients without IHC-detected *p53* expression.²⁴

CLASSIFICATION

Table 79-1 Histologic Classification of Lung Tumors

WHO ^a	
1. Squamous cell carcinoma	
Variants:	1.1 Papillary
	1.2 Clear cell
	1.3 Small cell
	1.4 Basaloid
2. Small cell carcinoma	
Variant:	2.1 Combined small cell carcinoma
3. Adenocarcinoma	
3.1 Acinar adenocarcinoma	
3.2 Papillary adenocarcinoma	
3.3 Bronchioloalveolar carcinoma	
3.4 Solid adenocarcinoma with mucin	
3.5 Adenocarcinoma with mixed subtypes	
Variants:	Fetal, mucinous ("colloid"), mucinous cystadenocarcinoma, signet ring, clear cell
4. Large cell carcinoma	
Variants:	4.1 Large cell neuroendocrine carcinoma
	4.2 Others
5. Adenosquamous carcinoma	
6. Carcinoma with pleomorphic, sarcomatoid, or sarcomatous elements	
7. Carcinoid	
7.1 Typical	
7.2 Atypical	
8. Carcinoma of salivary gland type	
8.1 Mucoepidermoid carcinoma	
8.2 Adenoid cystic carcinoma	
8.3 Epithelial–myoepithelial	
9. Unclassified	

^aWorld Health Organization. Adapted from World Health Organization *Classification of Tumors, Pathology and Genetics of Tumours of the Lung, Pleura, Thymus and Heart*. Lyon, France: IARC Press; 2004.

Epigenetic mechanisms of gene regulation also appear to participate in the tumorigenesis of lung cancer. In particular gene promoter inactivation by hypermethylation may be an important mechanism in the inactivation of tumor suppressor genes such as *p16^{INK4a}* (*p16*), an inhibitory regulator in the cyclin D-retinoblastoma cell cycle pathway. In patients with premalignant lesions such as squamous dysplasia and carcinoma in situ, both allelic loss and hypermethylation of *p16* have been identified, with associated decreases in p16 protein expression,²⁸ suggesting that loss of *p16* may be an important early event in NSCLC tumorigenesis.²⁹

Over the past decade genome-wide studies have revolutionized the study of complex disease processes including NSCLC. Efforts by groups comprising The Cancer Genome Atlas have yielded detailed and comprehensive characterization of mutational events across the entire cancer genome.^{30,31} Distinguishing those genes that appear to be involved causally in lung cancer tumorigenesis from those genes that are regulated secondarily is critical for our understanding of this disease and for the identification of potential targets for therapeutic intervention.

CLASSIFICATION

Table 79-2 TNM Classification for Staging System of Non–Small Cell Lung Cancer (6th ed.)

Stage		TNM Status
IA		T1 N0 M0
IB		T2 N0 M0
IIA		T1 N1 M0
IIB		T2 N1 M0
		T3 N0 M0
IIIA		T3 N1 M0
		T1–3 N2 M0
IIIB		T4 Any N M0
		Any T N3 M0
IV		Any T any N M1
TNM Definitions		
T	TX	Positive malignant cells, but primary tumor not visualized by imaging or bronchoscopy
	T0	No evidence of primary tumor
	Tis	Carcinoma in situ
	T1	Tumor ≤3 cm, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus ^a
	T2	Tumor with any of the following features of size or extent: >3 cm in greatest dimension Involves main bronchus, ≥2 cm distal to the carina Invades the visceral pleura

		Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
	T3	Tumor of any size that directly invades any of the following: chest wall (including superior sulcus tumors), diaphragm, mediastinal pleura, parietal pericardium; or tumor in the main bronchus <2 cm distal to the carina, but without involvement of the carina; or associated atelectasis or obstructive pneumonitis of the entire lung
	T4	Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, esophagus, vertebral body, carina; or tumor with a malignant pleural or pericardial effusion, or with satellite tumor nodule(s) within the ipsilateral primary tumor lobe of the lung ^b
N	NX	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastasis
	N1	Metastasis to ipsilateral peribronchial and/or ipsilateral hilar lymph nodes, and involvement of intrapulmonary nodes by direct extension of the primary tumor
	N2	Metastasis to ipsilateral mediastinal and/or subcarinal lymph node(s)
	N3	Metastasis to contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
M	MX	Presence of distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis present including metastatic tumor nodule(s) in the ipsilateral non–primary tumor lobe of the lung

^aThe uncommon superficial tumor of any size with its invasive component limited to the bronchial wall that may extend proximal to the main bronchus is classified as T1.

^bMost pleural effusions associated with lung cancer are caused by tumor. There are, however, some patients in whom the pleural fluid (more than one specimen) is negative for tumor on cytopathologic examination and in whom the fluid is nonbloody and is not an exudate. In cases in which these elements and clinical judgment dictate that the effusion is not related to the tumor, the patient should be staged T1, T2, or T3, with effusion excluded as a staging element. Pericardial effusion is classified according to the same rules.

2 Targeted molecular therapy has been shown to have clinical benefit notably for patients with advanced NSCLC. For example, among patients whose tumors are shown to carry specific mutations in the epidermal growth factor receptor (*EGFR*) gene, treatment with small molecule tyrosine-kinase inhibitors targeting *EGFR* has been associated with improved progression-free survival as demonstrated by several randomized trials.³² Whether such treatment regimens might be effective in the adjuvant setting for patients with earlier stage NSCLC who have undergone curative-intent lung resection has yet to be established, but is the focus of a recently initiated cooperative group trial. The Adjuvant Lung Cancer Enrichment Marker Identification and Sequencing Trials (ALCHEMIST) will evaluate patients with resected lung adenocarcinomas (stage IB to stage IIIA). Those subjects found to have tumors carrying activating *EGFR* mutations or the *ALK-echinoderm microtubule-associated protein-like 4* (*EML4*) fusion gene will be randomized for “maintenance” treatment with either erlotinib (*EGFR*) or crizotinib (*ALK* fusion), respectively, following completion of standard-of-care adjuvant chemotherapy with or without radiation therapy. Enrolled patients found to have neither of the targeted mutations will be followed in an observational study until tumor recurrence. These studies represent an exciting potential application of gene expression studies for use in determining patient prognosis, as well as guiding the

clinical management of lung cancer and preventing over- or undertreatment of patients.

NON–SMALL CELL LUNG CANCER

Diagnosis

The diagnosis of lung cancer should be directed by the presumed stage of disease at patient presentation. Accurate and reproducible TNM staging of lung cancer allows clinicians to provide consistent treatment of lung cancer and provides the basis for uniform reporting of clinical research across institutions and study groups. In 1997, revisions in the International System for Staging Lung Cancer ([Table 79-2](#)) were adopted by the American Joint Committee on Cancer (AJCC) and the Union Internationale Contre le Cancer (UICC), based on 5,319 cases of lung cancer.³ Revisions implemented for the most recent iteration of the TNM classification schema arose from evaluation of 67,725 cases of NSCLC with broad geographic diversity including subjects from Asia, Australia, Europe, and North America^{33,34} and addressed both T³⁵ and M³⁶ designations ([Table 79-3](#)), with no changes implemented for the current nodal designations ([Table 79-4](#)).³⁷ Stratification of patient survival, particularly among subjects with pathologic stage IB and IIA cancers, was more distinct with application of the 7th edition criteria ([Table 79-5](#)).

Guidelines for surveillance of the incidentally detected subcentimeter nodule (<8 to 10 mm) or larger solitary pulmonary nodule (8 to 10 mm or larger) have been published by the Fleischner Society for Thoracic Imaging and Diagnosis,³⁸ the American College of Chest Physicians³⁹ and others⁴⁰ and are incorporated in a suggested algorithm ([Algorithm 79-1](#)) for evaluation of these common incidental chest findings. As with any algorithm, assessment of patient risk factors (pretest probability) for cancer³⁹ as well as comorbidities³⁸ should be taken into consideration before following these guidelines in one's practice.

3 One recent goal in the diagnosis of lung cancer has been the early detection of tumors arising in asymptomatic high prevalence populations, for example, older patients with a history of tobacco use. Low-dose chest CT screening appears to reduce lung cancer–related mortality as demonstrated by two modern clinical trials,^{7,8} while remaining cost-effective.⁴¹

4 The aims of the initial evaluation of a patient with NSCLC are to determine whether distant metastatic disease is present and to assess the extent of intrathoracic disease. A multidisciplinary approach, involving input from pulmonary medicine, chest radiology, medical and radiation oncology, and thoracic surgery, should be undertaken in the selection of the most suitable testing for any individual patient. One general algorithm is provided ([Algorithm 79-2](#)). A thorough history and physical examination, combined with a plain chest radiograph and baseline laboratory data (complete blood cell count and measurement of serum sodium, calcium, alkaline phosphatase, and lactate dehydrogenase levels), can suggest the presence of metastatic disease. Common metastatic sites include the brain, supraclavicular lymph nodes, contralateral lung, bones, liver, and adrenal glands. Chest CT and FDG–PET body scans are obtained for noninvasive evaluation and metabolic characterization of suspected lung tumors and evidence of mediastinal or extrathoracic involvement. If necessary, biopsy by needle aspiration or operation can be performed to obtain confirmation of malignancy and to determine the extent of disease.

If the initial clinical evaluation does not suggest the presence of distant disease, the extent of further evaluation by various scans is controversial. Some physicians always perform a complete metastatic workup with CT of the chest and abdomen, CT or MRI of the brain, and FDG–PET scan. CT scan of the chest and upper abdomen as well as FDG–PET scan have become standard, as much to evaluate the extent of the primary tumor and the status of the mediastinal lymph nodes as to detect metastases in the ipsilateral or contralateral lung, liver, or adrenals. Additional scans in asymptomatic patients may detect the 5% to 10% of metastases that are occult, but these scans are not clearly cost-effective in patients with clinical stage IA tumors. In patients who are suitable candidates for operation, who have a suspicious solitary pulmonary nodule that is of indeterminate origin despite appropriate evaluation, excisional biopsy and subsequent lobectomy for resectable lung cancer should be pursued.⁴²

Multi-institutional studies have indicated a benefit for a combined modality approach in the treatment of stage IIIA NSCLC, consisting of neoadjuvant chemotherapy and radiation followed by resection.⁴³ Therefore tissue confirmation of mediastinal nodal involvement ([Table 79-4](#)) has implications not only for the staging but the management of patients who are otherwise candidates for resection of locoregionally advanced NSCLC.⁴⁴

Chest CT provides only anatomic clues for tumor involvement of mediastinal lymph nodes (enlargement greater than 10 mm), as demonstrated in a recent meta-analysis of over 3,400 evaluable patients, with a pooled sensitivity of 57% and specificity of only 82%. This meta-analysis also demonstrated that FDG (¹⁸F-2-fluoro-2-deoxy-D-glucose)–positron emission tomography (FDG–PET) scanning appears to provide increased sensitivity of 84% and specificity of 89% in over 1,100 patients studied for the detection of mediastinal malignancy.⁴⁵ Several single-institution and multi-institutional prospective studies have also indicated the superior diagnostic accuracy of FDG–PET imaging.^{46–48} Although the overall sensitivity and specificity of FDG–PET staging was 61% and 84%, respectively, there was a significant improvement with FDG–PET over chest CT in the detection of both hilar (N1) lymph node (42% vs. 13%, *p* = 0.0177) and mediastinal (N2 and N3) tumor involvement (58% vs. 32%, *p* = 0.004). Whereas FDG–PET scanning can increase the suspicion of malignancy, its negative predictive value for mediastinal lymph node involvement does not appear to be sufficient, with a false-negative rate reported as high as 13%.⁴⁹ PET evaluation of the solitary pulmonary nodule also appears to be somewhat insensitive, with a negative predictive value for benign lesions of only 57%, indicating a false-negative rate of 47%. Reliance on this modality could lead to delayed treatment for resectable early-stage (IA) NSCLC.⁵⁰ Integrated CT–PET imaging, in which concurrently performed chest CT provides anatomic correlation for positive PET findings, appears to provide more precise staging, particularly regarding tumor and nodal status,⁵¹ and also can be used to guide further invasive testing in the accurate staging of lung cancer.

CLASSIFICATION

Table 79-3 TNM Classification for Staging System of Non–Small Cell Lung Cancer (7th ed.)

Stage			TNM Status
IA			T1a or b N0 M0
IB			T2a N0 M0
IIA			T1 or 2a N1 M0
IIB			T2b N0 M0
			T2b N1 M0
			T3 N0 M0
IIIA			T3 or 4 N0 or 1 M0
			T1–3 N2 M0
IIIB			T4 N2 M0
			Any T N3 M0
IV			Any T any N M1
TNM Definitions			
T	TX	Positive malignant cells, but primary tumor not visualized by imaging or bronchoscopy	
	T0	No evidence of primary tumor	
	Tis	Carcinoma in situ	
	T1a	Tumor ≤2 cm, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus ^a	
	T1b	Tumor >2–3 cm, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus ^a	
	T2	Tumor >3 cm but ≤7 cm or tumor with any of the following features:	
		Involves main bronchus, ≥2 cm distal to the carina	
		Invades the visceral pleura	
		Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung	

		T2a Tumor >3 cm but ≤5 cm in greatest dimension, or with the above features but size cannot be determined
		T2b Tumor >5 cm but ≤7 cm in greatest dimension
	T3	Tumor >7 cm or one that directly invades any of the following: chest wall (including superior sulcus tumors), diaphragm, mediastinal pleura, parietal pericardium; or tumor in the main bronchus <2 cm distal to the carina, but without involvement of the carina; associated atelectasis or obstructive pneumonitis of the entire lung; or separate tumor nodule(s) in the same lobe
	T4	Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, esophagus, vertebral body, carina; separate tumor nodule(s) in a different ipsilateral lobe
N	NX	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastasis
	N1	Metastasis to ipsilateral peribronchial and/or ipsilateral hilar lymph nodes, and involvement of intrapulmonary nodes by direct extension of the primary tumor
	N2	Metastasis to ipsilateral mediastinal and/or subcarinal lymph node(s)
	N3	Metastasis to contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
M	MX	Presence of distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis present
		M1a separate tumor nodule(s) in a contralateral lobe; tumor with pleural nodules or malignant pleural (or pericardial) effusion ^b
		M1b distant metastases

^aThe uncommon superficial tumor of any size with its invasive component limited to the bronchial wall that may extend proximal to the main bronchus is classified as T1.

^bMost pleural (and pericardial) effusions associated with lung cancer are caused by tumor. There are some patients in whom the pleural fluid (more than one specimen) is negative for tumor on cytopathologic examination and in whom the fluid is nonbloody and is not an exudate. In cases in which these elements and clinical judgment dictate that the effusion is not related to the tumor, the patient should be staged T1, T2, T3 or T4, with effusion excluded as a staging element.

CLASSIFICATION

Table 79-4 The Mountain–Dresler Lymph Node Map

Nodal Station	Anatomic Landmarks
N2 nodes: All N2 nodes lie within the mediastinal pleural envelope	
1. Highest mediastinal nodes	Nodes lying above a horizontal line at the upper rim of the brachiocephalic (left innominate) vein where it ascends to the left, crossing in front of the trachea at its midline.
2. Upper paratracheal nodes	Nodes lying above a horizontal line drawn tangential to the upper margin of the aortic arch and below the inferior boundary of No. 1 nodes.
3. Prevascular and retrotracheal nodes	Prevascular and retrotracheal nodes may be designated 3A (anterior to the vessels) and 3P (prevertebral); midline nodes are considered to be ipsilateral.
4. Lower paratracheal nodes	The lower paratracheal nodes on the right lie to the right of the midline of the trachea between a horizontal line drawn tangential to the upper margin of the aortic arch and a line extending across the right main bronchus at the upper margin of the upper lobe bronchus, and contained within the mediastinal pleural envelope; the lower paratracheal nodes on the left lie to the left of the midline of the trachea between a horizontal line drawn tangential to the upper margin to the aortic arch and a line extending across the left main bronchus at the level of the upper margin of the left upper lobe bronchus, medial to the ligamentum arteriosum and contained within the mediastinal pleural envelope. Researchers may want to designate the lower paratracheal nodes as No. 4s (superior) and No. 4i (inferior) subsets for study purposes; the No. 4s nodes may be defined by a horizontal line extending across the trachea and drawn tangential to the cephalic border of the azygos vein; the No. 4i nodes may be defined by the lower boundary of No. 4s and the lower boundary of No. 4 as described above.
5. Subaortic (aortopulmonary window)	Subaortic nodes are lateral to the ligamentum arteriosum or the aorta or left pulmonary artery and proximal to the first branch of the left pulmonary artery and lie within the mediastinal pleural envelope.
6. Paraaortic nodes (ascending aorta or phrenic)	Nodes lying anterior and lateral to the ascending aorta and the aortic arch or the innominate artery, beneath a line tangential to the upper margin of the aortic arch.
7. Subcarinal nodes	Nodes lying caudal to the carina of the trachea but not associated with the lower lobe bronchi or arteries within the lung.
8. Paraesophageal nodes (below carina)	Nodes lying adjacent to the wall of the esophagus and to the right or left of the midline, excluding subcarinal nodes.
9. Pulmonary ligament nodes	Nodes lying within the pulmonary ligament, including those in the posterior wall and lower part of the inferior pulmonary vein.
N1 nodes: All N1 nodes lie distal to the mediastinal pleural reflection and within the visceral pleura	
10. Hilar nodes	The proximal lobar nodes, distal to the mediastinal pleural reflection and the nodes adjacent to the bronchus intermedius on the right; radiographically, the hilar shadow may be created by enlargement of both hilar and interlobar nodes.
11. Interlobar nodes	Nodes lying between the lobar bronchi.
12. Lobar nodes	Nodes adjacent to the distal bronchi.
13. Segmental nodes	Nodes adjacent to the segmental bronchi.
14. Subsegmental nodes	Nodes around the subsegmental bronchi.

Definition of the anatomic boundaries for each lymph node region facilitates correlation between findings at operation and findings on chest computed tomography. (After Mountain CF, Dresler CM. Regional lymph node classification for lung cancer staging. *Chest* 1997;111:1718.)

Ultimately tissue confirmation of noninvasive findings should be obtained, particularly in the setting of large, prospective trials being undertaken to determine the efficacy of neoadjuvant and adjuvant therapy.⁵² Noninvasive techniques for clinical staging, particularly chest CT, have a reported false-negative rate of approximately 10% to 15%. FDG–PET scan also has a reported false-positive rate of as high as 50%.⁴⁶ Clinical staging of NSCLC, particularly mediastinal lymph node involvement, can be accomplished by needle aspiration techniques from several approaches: transbronchial (TBNA) with or without endobronchial ultrasound (EBUS) guidance, transthoracic, or transesophageal. EBUS–TBNA is an accurate method for evaluation of the mediastinum, comparable to, if not better than, the accuracy of mediastinoscopy.⁵³ Transesophageal endoscopic ultrasound with fine needle aspiration (EUS–FNA) appears to be particularly useful for sampling of posterior mediastinal nodes such as the subcarinal, periesophageal, or aortopulmonary window stations, particularly in patients with mediastinal lymphadenopathy in these regions. Diagnostic yield is improved with practitioner experience, sampling needle size and onsite cytology examination to determine adequacy of the obtained samples.

Cervical mediastinoscopy remains an important diagnostic modality, particularly for sampling of smaller lymph nodes, or if larger sample sizes are needed either for assessment of tissue architecture, or for supplemental molecular studies. This modality has a procedural sensitivity greater than 90%, and specificity of 100%⁵⁴ as demonstrated in a large retrospective review of a single-institutional experience, including 1,745 patients, which demonstrated a reduction in “unnecessary” exploration, low morbidity (0.6%) and minimal perioperative mortality (0.05%).⁵⁵ For patients with clinically suspicious aortopulmonary lymph node involvement (stations 5 and 6), an area which is generally not accessible by standard mediastinoscopy, anterior mediastinotomy, extended cervical mediastinoscopy, or thoracoscopy can be performed.

Adapted from Goldwstraw P, Crowley J, Chansky K, et al. The IASLC Lung Cancer Staging Project: proposals for the revision of the TNM stage groupings in the forthcoming (seventh) edition of the TNM Classification of malignant tumours. *J Thorac Oncol* 2007;2:706–714.

Patients presenting with suspected NSCLC and a pleural effusion should undergo thoracentesis, followed by thoracoscopy, should initial cytology specimens be nondiagnostic. Those patients presenting with metastatic (stage IV) disease involving a solitary distant site should obtain tissue confirmation at the site of metastasis, if technically feasible. If noninvasive testing demonstrates multiple metastases (e.g., multiple liver, brain, or bone lesions), then diagnosis of the primary lesion might provide the most efficient means of diagnosis, followed by the initiation of palliative chemotherapy.⁵⁶

Algorithm 79-1. Management of the incidental solitary pulmonary nodule. Partially based on MacMahon H, Austin JHM, Gamsu G, et al. Guidelines for management of small pulmonary nodules detected on CT scans: a statement from the Fleischner Society. *Radiology* 2005;237:395–400.

Algorithm 79-2

Algorithm 79-2. Evaluation of the patient who presents with a pulmonary mass.

Although newer modalities of noninvasive imaging, such as FDG–PET imaging, have improved the accuracy of staging for lung cancer,^{8,49} these techniques still rely on factors such as tumor volume, tumor density, and metabolic activity. Unfortunately, current staging procedures do not yet have the sensitivity to detect all lymph node or distant hematogenous metastases.

Risk Assessment

Having established that resection is feasible, a significant number of patients with lung cancer cannot undergo operation due to associated comorbidities that increase operative mortality and postoperative morbidity. Age alone should not preclude patients with resectable disease from operation.⁵⁷ In a population with a high prevalence of prior or continuing tobacco use that has a greater predisposition to atherosclerotic cardiovascular disease, preoperative cardiovascular risk assessment with further noninvasive cardiac testing or coronary angiography, if indicated, should be considered.⁵⁸

Preoperative spirometry, particularly the forced expiratory volume in 1 second (FEV₁), as an assessment of patients' suitability for pulmonary resection is essential. Measurement of the diffusing capacity of the lung for carbon monoxide (DLCO) provides complementary data to standard spirometry, particularly for patients with evidence of interstitial lung disease or exertional dyspnea. Generally, if a patient demonstrates FEV₁ > 2 L (>60% predicted) or DLCO >50% predicted, further evaluation of pulmonary capacity prior to resection is not necessary.^{59,60} Patients with limited pulmonary reserve, including those with FEV₁ <1.2 L (40% predicted) or DLCO 35% to 40% predicted, are at higher risk for significant morbidity or mortality following anatomic resection, and should undergo further evaluation.⁶¹

The predicted postoperative (ppo) lung function in patients with marginal pulmonary function can be calculated as follows: ppoFEV₁ (% predicted) = preoperative FEV₁ (% predicted) × (1 – fraction of total number of anatomic segments to be resected). Patients with ppoFEV₁ <0.8 L, or 35% to 40% predicted, are likely at substantially increased risk for perioperative death or complication.^{62,63} For patients with heterogeneous lung disease including upper lobe predominant emphysema, quantitative perfusion scanning provides a more accurate assessment. To obtain the ppoFEV₁ (% predicted), the preoperative FEV₁ (% predicted) is multiplied by (100% – %perfusion of the area to be resected).

Preoperative room-air arterial blood gas testing can identify patients at greater risk for perioperative complications or death. In particular, patients with arterial oxygen concentration less than 60 mm Hg, PaCO₂ greater than 45 mm Hg, or oxygen saturation less than 90% may be at greater risk for

pulmonary resection.

If available, further testing with formal cardiopulmonary exercise testing (CPET) to calculate maximal oxygen consumption ($\text{Vo}_2 \text{ max}$) may allow further risk stratification in such marginal patients. In several series, patients with a $\text{Vo}_2 \text{ max} < 10$ to 15 mL/min/kg were at high risk for postoperative complication, whereas those with $\text{Vo}_2 \text{ max} > 20 \text{ mL/min/kg}$ underwent operation without complication or death.⁶³ These findings were corroborated by a recent cooperative group study (CALGB 9238) conducted to determine whether pulmonary resection could be accomplished safely in patients with peak exercise oxygen capacity $> 15 \text{ mL/min/kg}$, regardless of FEV_1 . In this prospective study of 346 patients who underwent thoracotomy for NSCLC, there were 86 subjects whose peak exercise oxygen capacity was less than the threshold of $< 15 \text{ mL/min/kg}$, or 60% of predicted. This group experienced significantly more cardiorespiratory complications, respiratory failure, or death than the remaining subjects whose peak exercise oxygen capacity was $> 15 \text{ mL/min/kg}$. From these data, the authors concluded that patients with peak exercise oxygen capacity $> 15 \text{ mL/min/kg}$, even if FEV_1 and/or DLCO were less than 70% predicted, could undergo pulmonary resection with curative intent.⁶⁴

Algorithm 79-3. This algorithm illustrates the preoperative functional evaluation prior to lung cancer resection. FEV_1 , forced expiratory volume in 1 second; DLCO, carbon monoxide diffusing capacity; ppo, predicted postoperative values; $\text{Vo}_2 \text{ max}$, maximum oxygen uptake.

Informal exercise testing, particularly stair-climbing, may also aid the clinician in determining a patient's suitability for resection. Patients who are able to climb at least two flights of stairs likely will tolerate pneumonectomy, whereas those who cannot climb a single flight likely will not tolerate lobectomy. Furthermore, oxygen desaturation, greater than 4%, during exercise testing may also be an indicator for increased risk of perioperative complication. Careful preoperative physiologic assessment will allow the clinician to identify patients at increased risk for perioperative complication or death, and allow such patients to make an informed decision regarding operation.⁶⁵ Measures to minimize postoperative complications, including aggressive efforts to encourage smoking cessation, pre-and postoperative chest physiotherapy, incentive spirometry, early extubation and mobilization, and the use of postoperative thoracic epidural analgesia, are important for all patients undergoing pulmonary resection, especially those with marginal pulmonary function (Algorithm 79-3).

Treatment

5 Pulmonary resection, with definitive tumor staging, remains the mainstay of treatment for stage I, II, and selected stage III NSCLC. The extent of resection, segmentectomy, lobectomy, bilobectomy, or pneumonectomy, is determined by the location and size of the primary tumor and also whether adjacent

bronchopulmonary nodes are involved. At operation, tumor extent is evaluated by examination of the parietal pleura, pericardium, and mediastinal structures. Complete resection must achieve microscopically negative bronchial and vascular margins. Potential postoperative complications after pulmonary resection are listed in [Table 79-6](#).

COMPLICATIONS

Table 79-6 Postoperative Complications after Pulmonary Resection

Complication	Incidence (%)
Atrial arrhythmia	2.9–14.4
Prolonged air leak	4–7.6
Pneumonia	1–2.5
Subcutaneous emphysema	0.8–1.1
Myocardial infarction	0.4–0.9
Recurrent laryngeal nerve injury	0.4–0.7
Bronchopleural fistula	0.3–0.5
Respiratory failure	0.1–5.5
Hemorrhage	0–1.5
Empyema	0–1.1
Mortality	0.7–1.4%

*Includes thoracoscopic and open series. Based on Berry MF and D’Amico TA. Complications of thoracoscopic pulmonary resection. *Semin Thorac Cardiovasc Surg* 2007;19:350–354.

Figure 79-1. A: Posteroanterior chest radiograph shows an elevated left hemidiaphragm, suggestive of phrenic nerve involvement by the mass. B: Lateral chest radiograph shows extension of the mass into the anterior chest wall (*arrows*). C: Computed tomography suggests both pericardial and chest wall involvement (*arrows*). At thoracotomy, the chest wall, phrenic nerve, and pericardium were found to be involved. All were resected en bloc with the tumor.

If a tumor extends directly into the chest wall, diaphragm, or pericardium, an en bloc resection of the adjacent involved structure should be performed with the pulmonary resection. Reconstruction is performed as necessary (Fig. 79-1). If extensive endobronchial involvement is present without involvement of the surrounding vascular or lymphatic structures, the tumor can sometimes be removed completely by lobectomy with segmental resection of the bronchus and/or pulmonary artery (bronchovascular sleeve resection), thus preserving lung function.

Patients with centrally located tumors should undergo sleeve lobectomy rather than pneumonectomy if complete resection can be achieved and such an approach is technically feasible. Several retrospective studies^{66–70} have demonstrated that operative mortality is reduced among patients undergoing sleeve lobectomy (0% to 5.2%) when compared with patients undergoing pneumonectomy (1.7% to 8.9%). Moreover, overall 5-year survival is improved among patients undergoing sleeve resection, particularly among those with N0 or N1 nodal status. For peripherally located clinical stage I tumors, particularly among patients with limited pulmonary reserve or those at high risk from other comorbidities, segmental or nonanatomic “wedge” resection can be performed. Sublobar resection also may be appropriate for patients with good pulmonary function and who otherwise would be candidates for lobectomy (Table 79-7). Whether such patients are at greater risk for locoregional recurrence, as suggested in earlier series^{71–73} but not borne out in modern series,⁷⁴ is under investigation in an ongoing multi-institutional prospective and randomized cooperative group clinical trial (CALGB 140503).

Although noninvasive techniques for preoperative assessment of mediastinal nodes have improved, nodal status should be confirmed by intraoperative mediastinal lymph node sampling or mediastinal lymph node dissection. Accurate pathologic staging provides not only prognostic information but is also important in the decision on whether to proceed with adjuvant chemotherapy. Systematic sampling should include tissue from at least three N2 lymph node stations, using standard nomenclature and numbering as depicted in (Table 79-4). Complete mediastinal lymph node dissection does not appear to confer increased perioperative morbidity⁷⁵ but also does not confer a survival advantage for patients with early stage (T1, T2, N0, and N1) NSCLC as staged at the time of lung resection. The long-term survival impact of mediastinal lymph node dissection has not been evaluated well for patients with clinical staging obtained solely by radiography or for patients with higher-stage NSCLC.^{76–78}

INDICATIONS

Table 79-7 Criteria for Sublobar Pulmonary Resection

Peripheral nodule ≤2 cm with at least one of the following:
■ Pure adenocarcinoma in situ (AIS) histology
■ Nodule has ≥50% ground-glass appearance on CT
■ Radiologic surveillance confirms a long doubling time (≥400 days) and minimum margins (≥2 cm or ≥ the size of the nodule)

Survival

Long-term survival after resection for NSCLC is linked to the pathologic stage of disease. The overall 5-year survival rates are shown in Table 79-5. They range from 60% to 70% for stage I tumors, from 40% to 50% for stage II tumors, and from 15% to 30% for stage IIIA tumors. Nodal involvement has the strongest adverse influence on survival. Large peripheral tumors that extend directly into the chest wall without nodal involvement (T3N0) are associated with a 5-year survival rate of 40% after complete resection, whereas involvement of mediastinal nodes is associated with only a 20% survival rate.

Some series suggest that histology also affects survival. In node-negative NSCLC, large cell neuroendocrine differentiation conferred worse survival than other types of NSCLC.⁷⁹ Different adenocarcinoma subtypes, particularly in more advanced tumors, also appear to confer worse prognosis, but the influence of histology has not been described uniformly in series to-date.⁸⁰ Delineation of tumor biology by more refined histologic and molecular analyses will be needed to define which patients might be at increased risk for recurrence or treatment resistance.

Patterns of Recurrence

The predominant sites of relapse for all stages of NSCLC after resection are distant metastases. Approximately 30% of recurrences are locoregional with tumors of both squamous and nonsquamous histology.⁸¹ For all stages of disease, the brain is the single most common site of relapse, and brain metastases occur more frequently with nonsquamous tumors. Other common metastatic sites include bone, ipsilateral or contralateral lung, liver, and the adrenal glands.^{81,82}

At least 60% of recurrences develop in the first 2 years after operation, and virtually all recurrences related to the original primary tumor occur within 5 years after surgery. Even the small proportion of patients with stage II or III disease who survive 5 years are likely to survive 10 years or more postoperatively. Recurrences of the original primary tumor are uncommon after 5 years, and after that time the occurrence of new pulmonary cancers becomes the dominant problem. The risk for development of a second lung cancer in patients with a prior history of cancer resection for NSCLC is estimated to be 2% to 3% per patient per year,⁸³ with a second lung cancer developing rarely in never-smokers at the time of initial resection, and at rates of 1.8% per patient-year in former smokers and 2.7% per patient-year in current smokers.⁸⁴ Patients also face a consistent risk for the development of new, nonpulmonary primary cancers during the first 5 years after operation and thereafter. New, nonpulmonary malignancies develop in a wide variety of sites, most commonly breast, colon, and prostate cancers.⁸¹

These data underscore the importance of long-term follow-up after resection of early-stage NSCLC. Guidelines provided by the American College of Chest Physicians⁸⁵ and the National Comprehensive Cancer Network support regular oncologic surveillance after curative-intent lung resection. In coordination with the primary or referring physician, recommended surveillance includes directed clinical assessment, every 6 to 12 months the first 2 years and then annually thereafter. Although there is no single modality to detect recurrence, follow-up should include a combination of history, physical examination, serial chest radiographs, and low-dose spiral chest CT. Neither PET scan nor MRI studies are recommended as part of routine surveillance.^{85,86}

Adjuvant Therapy for NSCLC

The risk for recurrent disease, even after resection of early-stage NSCLC, has led to efforts to improve overall survival rates through the use of adjuvant therapy, even though no specific method is available to identify which patients will relapse. Various types of adjuvant therapy have been tested, including immunotherapy,^{87–89} radiation, chemotherapy, and combined chemotherapy and radiation.

Radiation has been evaluated extensively as adjuvant therapy. Although early retrospective series suggested that postoperative radiation therapy (PORT) potentially improved overall survival,^{90–92} subsequent relatively small randomized trials comparing adjuvant radiation with no further treatment failed to demonstrate any significant difference in overall survival.^{93–97} Distant metastases remained the most common form of recurrent disease and were not affected by postoperative radiation to the mediastinum. Several of these trials^{93,94,96,97} showed that radiation significantly decreased the risk for locoregional recurrence in tumors of all histologic types (Table 79-8). A meta-analysis of several randomized controlled studies of postoperative radiation therapy suggested an adverse effect on survival, particularly among patients treated with PORT with early-stage (I or II) lung cancer.⁹⁸ Postoperative thoracic radiation appears to be appropriate for patients who are at high risk for locoregional recurrence such as those found to have unexpected mediastinal (N2 or N3) nodal disease or those with evidence of residual tumor (R1 resection) at surgical margins.⁹⁹

RESULTS

ANITA, Adjuvant Navelbine International Trialist Association; CAP, cyclophosphamide, doxorubicin, cisplatin; CCNU, J-12-chlorethyl-3-cyclohexyl-J nitrosourea; CDDP, cisplatin; COPAC, cyclophosphamide, doxorubicin, cisplatin, vincristine, lomustine; Cytosan, cyclophosphamide; DFS, disease-free survival; EP, etoposide, cisplatin; HN2, nitrogen mustard; IALT, International Adjuvant Lung Cancer Trial; M, mitomycin C; MTX, methotrexate; NS, not significant; no Rx, no adjuvant treatment; RT, radiation; UFT, tegafur plus uracil; Vnb, vinorelbine; VP, vindesine, cisplatin.

Because distant metastases are the predominant mode of relapse after resection of early-stage NSCLC, multiple randomized trials (Table 79-9) have been performed to determine if postoperative adjuvant chemotherapy improves survival. Early trials evaluated agents, including nitrogen mustards, cytosan, methotrexate, and nitrosourea, now known to have no activity in NSCLC.^{100–103} More recently, several studies have demonstrated that cisplatin-based chemotherapy regimens appear to provide a modest survival benefit. A meta-analysis of 9,387 patients entered into 52 randomized clinical trials showed a 5% survival benefit at 5 years for adjuvant cisplatin-based chemotherapy in comparison with surgery alone. Trials comparing adjuvant radiation with radiation plus chemotherapy showed an absolute survival benefit of 4% at 2 years in favor of combined-modality treatment.¹⁰⁴

Recent trials of adjuvant chemotherapy in patients with completely resected NSCLC appear to indicate a therapeutic benefit. The multicenter International Adjuvant Lung Cancer Trial evaluated the effect of cisplatin-based adjuvant chemotherapy on survival after complete resection of NSCLC. A total of 1,867 patients with resected stage I, II, or III NSCLC were randomized to receive cisplatin-based chemotherapy, cisplatin-based chemotherapy and radiation, radiation alone, or no adjuvant treatment. Individual institutions administered additional chemotherapeutic agents at their discretion (“open-choice design”), with nearly half of the treated patients receiving cisplatin (100 mg/m²) and etoposide for 3 or 4 cycles. The total dose delivered of cisplatin was greater than 240 mg/m² for 73.8% of treated patients. Additional agents used were vinorelbine, vinblastine, or vindesine. Cisplatin dosing varied from 80 to 120 mg/m²/cycle, for a total expected dose of 300 to 400 mg/m². Statistically significant benefits were observed for both overall (absolute difference, 4.1%) and disease-free (absolute difference, 5.1%) survival at 5 years, for patients treated with cisplatin-based chemotherapy, with or

without adjuvant radiation.⁴ Planned radiotherapy did not appear to provide any added benefit. In subgroup analysis, the benefits of cisplatin-based adjuvant chemotherapy appeared to confer the greatest benefit upon patients with stage III NSCLC. In longer-term follow-up, disease-free survival HR remained improved at 0.88 (95% CI 0.78 to 0.98, $p = 0.02$) for patients receiving adjuvant therapy over 7 years following operation, but the previously observed improvement in overall survival was no longer statistically significant with HR 0.91 (95% CI 0.81 to 1.02, $p = 0.10$).¹¹⁵

Several subsequent studies support the use of adjuvant chemotherapy, particularly in stage II and III lung cancer. These studies are summarized in recent meta-analyses of combined modality therapy in the treatment of resectable lung cancer,^{116,117} which confirm the benefit of adjuvant chemotherapy following lung cancer resection for curative intent, with an absolute improvement in survival of 4% to 5.4% at 5 years of follow-up or beyond.

Notably, clinical trials evaluating adjuvant treatment for resected NSCLC have shown that approximately half of all patients actually received the planned dose of chemotherapy.^{105,109} It remains to be determined whether patients undergoing minimally invasive approaches to pulmonary resection can tolerate adjuvant chemotherapy better than similar patients recovering from open operations. Thoracoscopic lobectomy, for example, may facilitate subsequent adjuvant chemotherapy.¹¹⁸ In a series of 100 patients, 43 underwent thoracotomy and 57 had pulmonary resection performed by thoracoscopy. Those undergoing thoracoscopic resection were found to have a higher compliance rate with adjuvant treatment. Chemotherapy doses were delayed in significantly fewer patients in the thoracoscopic group (18% vs. 58%). Chemotherapy doses were reduced in only 26% of subjects undergoing thoracoscopy compared with 49% in the thoracotomy group. In addition, a significantly higher percentage of thoracoscopy patients received 75% or more of the planned regimen. There was no significant difference in the time to initiation of chemotherapy or toxicity.

Treatment of Stage III Disease

Stage III NSCLC indicates locoregionally advanced disease that encompasses several anatomic subsets which vary considerably in the likelihood that resection will provide durable oncologic benefit. Stage IIIB is generally considered unresectable. There is no role for resection for patients with T4 (stage IIIB) disease due to malignant pleural or pericardial effusion, infiltration of the heart, or those with contralateral or supraclavicular nodal metastases (N3). Several small series from specialized centers have demonstrated that curative intent operation can be considered for selected patients with invasion of mediastinal structures such as the superior vena cava, left atrium, carina, vertebrae or aorta, with consideration for induction chemoradiation, to “downstage” such tumors.^{119–121} These series indicate that complete resection is essential to obtain survival benefit from this approach.

Stage IIIA includes patients with extrapulmonary disease involving the ipsilateral hemithorax, that is, T3N1 and T1–3N2. The management of patients with stage IIIA disease due to mediastinal nodal involvement (N2) has evolved considerably over the last several decades. Local therapy alone for curative intent, that is, pulmonary resection or definitive-dose radiation therapy is not recommended.

Role of Resection

The most controversial and complex part of the treatment of stage IIIA NSCLC is the management of patients with N2 disease. Reported 5-year survival rates after resection for N2 disease are usually 20% to 30% but range from zero to 40%. This variation reflects the extent of mediastinal nodal involvement, the T status of the primary tumor, and the ability to perform a complete resection. With respect to mediastinal nodal involvement, adverse prognostic factors include the presence of extracapsular nodal disease, multiple levels of involved lymph nodes and superior mediastinal nodal metastases.^{122,123}

Rationale for Neoadjuvant Therapy

Although some patients with “minimal” N2 disease survive for long periods of time after resection, most have more extensive nodal involvement and do not benefit from either surgery or radiation therapy alone as their primary treatment. Efforts to improve outcomes following local control strategies have been limited by relapse at distant sites. Two early, randomized clinical trials challenged the concept of resection as the primary treatment for any patient with N2 disease. Rosell and colleagues^{124,125} randomized 60 patients with stage IIIA NSCLC (16 of whom did not have N2 disease) to undergo resection or to receive three cycles of cisplatin-based chemotherapy followed by resection. The median survival of the patients who received preoperative chemotherapy was significantly longer (26 vs. 8 months) than the survival of patients who underwent only resection. A study of similar design from the

M. D. Anderson Cancer Center corroborated these results.^{126,127} Both trials were stopped early because of highly significant differences between the two study arms. These two studies suggested that it is appropriate to consider all patients with N2 disease diagnosed at mediastinoscopy for induction chemotherapy. Since pretreatment mediastinoscopy was not mandated in either trial, some patients who did not have N2 disease were included. The results of these trials are not universally accepted because of the small numbers of patients enrolled, the lack of systematic pretreatment staging, and the unusually poor survival of the patients in the control (surgery-only) arms.

Early Trials of Neoadjuvant Therapy

The concept of preoperative therapy followed by resection (*neoadjuvant therapy*) dates back to 1955, when Bromley and Szur¹²⁸ used radiation (at an average dose of 47 Gy) to treat 66 patients before resection. At operation, no viable tumor was found in 29 of 62 (47%) patients, but 10 patients died of complications in the first month, and only two patients survived to 5 years after operation. At the time, the natural history of NSCLC was not well understood, the methods of staging before resection not very accurate, and the risk for distant metastases not fully recognized. Effective chemotherapy did not exist and it was hoped that an approach that increased resectability might lead to better long-term survival. Thus, early neoadjuvant trials focused on the use of preoperative radiation.

Several subsequent studies further explored this approach.¹²⁹ All these trials were flawed by a lack of pretreatment staging, by the use of widely varying amounts of radiation, and by excessively long intervals between irradiation and resection. Nonetheless, it became apparent that aggressive local treatment did not improve long-term survival, even though radiation provided local control in a significant number of patients. The development of distant metastases in 50% to 80% of patients during or shortly after treatment underscored the need for systemic therapy in stage III NSCLC.

Recent Trials of Neoadjuvant Therapy

Because of a better understanding of the natural history of early-stage lung cancer and more universal adoption of the UICC/AJCC TNM staging system, recent trials have defined more uniform patient populations, so that it has been easier to interpret trial results. Although many different treatment regimens have been used in neoadjuvant trials, they can be grouped into three major categories: (a) chemoradiation without resection, (b) chemotherapy followed by resection, and (c) chemoradiation followed by resection.

Trials of Chemoradiation without Resection

These trials cannot be equated with trials of neoadjuvant therapy that include resection because patients entered into nonsurgical trials are staged clinically without tissue confirmation of mediastinal lymph node involvement. Therefore, nonsurgical trials include a mix of patients with stage IIIA and IIIB cancers, and might even include some patients with earlier-stage disease who were thought erroneously to have stage III disease because of benign mediastinal adenopathy diagnosed only by axial chest imaging.

With the acceptance of chemotherapy and radiation as standard treatment, attention has focused recently on the optimal means to deliver both modalities.¹³⁰ Several studies have demonstrated that concurrent treatment is superior to sequential chemoradiotherapy. A cochrane database systematic review identified fourteen randomized studies comparing concurrent chemoradiation and radiation therapy alone. In this meta-analysis of 2,393 subjects, concurrent therapy was associated with a reduction in risk of death at 2 years (RR 0.93; 95% CI 0.88 to 0.98; $p = 0.01$) and improved 2-year progression-free survival, locoregionally (RR 0.84; 95% CI 0.72 to 0.98; $p = 0.03$) or distant (RR 0.90; 95% CI 0.84 to 0.97; $p = 0.005$). Concurrent chemoradiotherapy also had improved survival compared with sequential chemotherapy and radiation (RR 0.86; 95% CI 0.78 to 0.95; $p = 0.003$). In a separate meta-analysis of studies evaluating the addition of sequential or concurrent chemotherapy to radiation therapy in over 1,200 patients, a substantial overall survival benefit was observed for patients receiving concurrent treatment, with an absolute benefit of 5.7% (from 18.1% to 23.8%) at 3 years and 4.5% at 5 years (from 10.6% to 15.1%).¹³¹ Although concurrent chemoradiation was associated with less locoregional disease progression, no significant differences were observed between these two treatments, concurrent or sequential therapy, in terms of distant disease progression.¹³¹ Toxicities, particularly esophagitis, also were greater for patients receiving concurrent chemoradiation.^{131,132}

Trials of Neoadjuvant Therapy with Resection

These trials have used two different treatment strategies, induction chemotherapy alone or concurrent chemoradiation before resection. The rationale for chemotherapy alone as induction treatment is that it potentially allows the use of a more intense dose and the use of some drugs, such as mitomycin, that cannot be administered in conjunction with radiation. Proponents of this approach also believe that chemotherapy is as effective as induction treatment as is combined chemoradiation, and that separating the two modalities allows irradiation to be used postoperatively, when a higher total dose can be given. Proponents of concurrent preoperative chemoradiation believe that this approach provides adequate systemic treatment of micrometastatic disease and more effective control of bulky primary and mediastinal tumors.

Neoadjuvant Trials of Chemotherapy Alone before Resection

One of the best-known early trials to demonstrate the feasibility of combining induction chemotherapy with subsequent pulmonary resection in patients with stage III NSCLC was developed by Martini et al.¹³³ at Memorial Sloan-Kettering Cancer Center. In 1984, this group initiated a trial of high-dose, cisplatin-based (120 mg/m²) chemotherapy followed by resection for patients with clinical N2 disease. Vindesine or vinblastine and subsequently mitomycin were added to form the so-called “MVP” regimen. Postoperative radiation was given to patients who had persistent mediastinal nodal tumor at thoracotomy, and all patients received two additional cycles of chemotherapy postoperatively. In 136 patients treated from 1984 to 1991, the major response rate to induction chemotherapy was 77% (105/136), and the complete resection rate was 65% (89/136). A complete pathologic response was noted in 19 patients (21%) at the time of resection. The overall survival at 5 years was 17% and the median survival was 19 months; a distinct improvement over the historical survival for this group of patients. Seven treatment-related deaths (5%) occurred in this study, five of which were postoperative.

A phase II trial, reported by the CALGB in 1995, of induction chemotherapy enrolled 74 patients, treated with two cycles of cisplatin (100 mg/m² on days 1 and 29) and vinblastine (5 mg/m² per week) without mitomycin followed by resection for patients with mediastinoscopy-proven stage IIIA N2 disease.¹³⁴ In addition, two cycles of chemotherapy and 59.4 Gy of radiation were given postoperatively. Sixty-three patients (85%) had either an objective response or stable disease after induction therapy and underwent thoracotomy, with operative mortality rate of 3.2%. Twenty-three patients (37% of thoracotomies, 31% of all patients) had a complete resection, with 3-year survival of 46%. The overall 3-year survival was 23%. The lower resectability rate in this trial than in the study performed at Memorial Sloan-Kettering potentially reflected both the multi-institutional nature of this trial and the use of a less intensive chemotherapy regimen (primarily because of the omission of mitomycin). The overall long-term survival appeared similar for the two trials.

Trials of Induction Chemoradiation Followed by Resection

The second approach to combined-modality therapy and resection for stage III NSCLC has been to combine chemotherapy and radiation preoperatively (Table 79-10). This strategy aims to control micrometastatic disease while utilizing the synergism of concurrent radiation and chemotherapy to reduce tumor bulk in the primary site and mediastinum.

The largest reported phase II neoadjuvant trial of concurrent chemotherapy and radiation was a multi-institutional study performed by the Southwest Oncology Group.¹³⁸ Both stage IIIA and stage IIIB patients were entered, although notably, pathologic documentation of the initial tumor stage, usually by mediastinoscopy, was required. The induction regimen included two cycles of cisplatin (50 mg/m² on days 1 and 8) and etoposide with 4,500 cGy of concurrent radiation in 25 fractions. All patients underwent thoracotomy unless their disease progressed. The objective response rate to induction therapy in the 126 eligible patients was 59%. The resectability rates were 85% for the IIIA N2 group and 80% for the IIIB group. Nearly two-thirds of the patients had no viable tumor or only minimal residual foci of tumor in their surgical specimens. The 3-year survival rate was 27% for the IIIA group and 24% for the IIIB group, with median survival of 13 and 17 months, respectively. The best predictor of survival after surgery was the absence of tumor in the mediastinal nodes at surgery (3-year survival of 44%). The majority of recurrences were distant, and the brain was the single most common site. The operative mortality rate was 6%, and the overall treatment-related mortality was 10%. An important finding of SWOG 8805 was that survival was the same for patients with stage IIIB NSCLC by virtue of T4 tumor status and patients with stage IIIA N2 disease. Patients with N3 disease had a poor overall survival. Importantly, the long-term follow-up of this study showed that the survival rates at 3 years were sustained at 6 years.¹⁴² Important differences between the Southwest Oncology Group trial and

earlier neoadjuvant trials were the careful documentation of pretreatment stage, the use of a higher dose of continuous radiation (4,500 cGy rather than 3,000 cGy of continuous or 4,000 cGy of split-course radiation), and the fully concurrent manner in which the chemotherapy and radiation were administered.

A North America Intergroup clinical trial sought to determine whether neoadjuvant therapy including resection is superior to nonsurgical treatment with chemotherapy and higher-dose radiation in patients with stage IIIA NSCLC. In the Intergroup 0139/RTOG 9309 trial,^{43,140} patients with proven pN2, stage IIIA NSCLC were randomized to receive neoadjuvant chemotherapy with concurrent thoracic RT (TRT) followed by operation or continuation with definitive TRT.

Of 429 patients accrued over 92 months, 396 patients were considered eligible, and were treated with cisplatin (50 mg/m²), on days 1 and 8, and etoposide (50 mg/m²), on days 1 to 5, every 3 weeks for 2 cycles, as well as 45 Gy TRT. Patients randomized to resection (*n* = 202) underwent operation 4 to 6 weeks later. Patients randomized to definitive radiation (*n* = 194) continued without break to a total of 61 Gy. Following operation or completion of TRT, consolidation with 2 cycles of cisplatin and etoposide was given. Of note, less than two-thirds of patients undergoing operation received consolidation treatment, compared with over 75% of patients receiving chemoradiation only. There was no mortality in either group during induction chemoradiation. Mortality in the surgical treatment arm was 8%, with 14 of 16 deaths occurring in patients undergoing pneumonectomy.

RESULTS

Table 79-10 Results of Representative Neoadjuvant Trials for Stage III Non–Small Cell Lung Cancer: Induction Chemoradiotherapy Followed by Resection

Study (Reference)	No. of Patients	Chemotherapy	Radiotherapy (Gy)	Survival	
				Median (mo)	Overall (%)
Rush–Presbyterian, Faber et al. ¹³⁵	IIIA: 85 (including 19 N0)	CDDP (60 mg/m ²) + 5-FU ± VP-16 × 4	40(S), 20 fractions	21.7	40 (3 yrs)

CALGB, Cancer and Leukemia Group B; LCSG, Lung Cancer Study Group; RTOG, Radiation Therapy Oncology Group; SWOG, Southwest Oncology Group; 5-FU, 5-fluorouracil; CDDP, cisplatin; Vbl, vinblastine; VP-16, etoposide; (C), continuous course; (H), Hyperfractionated; (S), split course; PORT, postoperative radiation therapy; PFS, progression-free survival; OS, overall survival.

The median follow-up for the study population was 23 months (range 1 to 125 months). Progression-free survival (PFS) was improved from a median of 10.5 months to 12.8 months, and 5-year PFS from 11% to 22% with the addition of surgery. There appeared to be improved local control with the addition of surgery, with local failure occurring in only 10% of surgically treated patients compared with 22% in the nonsurgical group, although this was not statistically significant. However, no statistically significant differences were seen in overall survival, with 5-year survival of 20% and 27% for the chemoradiation alone and chemoradiation and surgery groups, respectively. This study indicated that carefully selected patients with N2-positive stage IIIA NSCLC can be treated with multimodality therapy including resection.

The role of surgery for patients whose tumors appear to require pneumonectomy remains controversial as well. In the recently published German Lung Cancer Study Group trial, patients were randomized to induction chemotherapy (cisplatin and etoposide) followed by chemoradiation (concurrent carboplatin and vindesine) and then by resection, or induction chemotherapy followed by surgery alone. Of 524 eligible patients, randomized and started on treatment, 296 underwent operation and 272 were resectable. In an intention-to-treat analysis of randomized, eligible patients, no

differences in progression-free or overall survival were observed between the treatment groups. Patients receiving preoperative chemoradiation were more likely to achieve complete resection among those with resectable tumors (98/131 vs. 84/141, $p = 0.008$), and were more likely to have evidence for mediastinal downstaging and pathologic response, but again with no significant difference observed in progression-free or overall survival. Of 104 patients who required pneumonectomy, including 39 on the right, mortality was slightly greater among patients treated with preoperative chemoradiation (7/50 vs. 3/54), but this was not statistically significant.¹⁴¹ Parenchymal-preserving bronchoplastic techniques also can be considered for those patients who might otherwise require pneumonectomy.¹⁴³ Whether such technically challenging approaches can be undertaken in the setting of recent radiation therapy remains to be established.

Stimulated by the promising results of the Southwest Oncology Group 8805 trial for patients with T4 disease, Grunenwald et al.¹²⁰ performed a phase II trial of similar design for stage IIIB T4 NSCLC. The induction regimen consisted of cisplatin (100 mg/m²), 5-fluorouracil, and vinblastine with 45 Gy of concurrent hyperfractionated (twice daily) radiation. Of 25 patients enrolled, 16 were subsequently eligible for surgery, and 12 had complete resection. No induction treatment-related or operative deaths occurred. This study confirmed that complete resection after induction therapy is feasible in a significant number of stage IIIB T4 tumors, a subset of stage IIIB tumors previously considered inoperable under any circumstances.

Current Status of Neoadjuvant Therapy and Resection

Clinical trials evaluating neoadjuvant therapy have demonstrated the feasibility of induction chemotherapy and resection for the treatment of stage III NSCLC. Most studies showed improved rates of resectability and survival in comparison with the historical experience for resection or radiation alone. The optimal treatment approach to these locally advanced tumors has not yet been fully defined, especially because neoadjuvant trials have varied with respect to eligibility criteria, inclusion of both stage IIIA and stage IIIB tumors, accuracy of pretreatment staging, and type of induction regimens. The response, resectability, and survival rates have not been uniformly reported. In some studies, instead of reporting results as a percentage of the total number of patients entered into the study, the authors reported resectability rates as a percentage of the patients with a radiographic response, and only the survival rates of patients who underwent resection were emphasized.

The potential toxicity of neoadjuvant regimens should not be overlooked. Induction regimens including high-dose cisplatin (≥ 100 mg/m²) or radiation doses of 4,000 to 4,500 cGy have been well tolerated, but radiation doses of 5,500 cGy or higher have been associated with an excessive risk for postoperative ARDS and bronchial stump leak. Good response rates have been achieved with chemotherapeutic agents including paclitaxel, docetaxel, gemcitabine, and carboplatin, which are tolerated better by patients. Determining the contribution of these agents in combined-modality therapy will require further trials, especially as the major form of relapse continues to be distant metastatic disease.

Future Directions

6 In addition to new chemotherapeutic agents, new radiation techniques, such as hyperfractionated or accelerated schedules, also merit further exploration in neoadjuvant trials with concurrent chemotherapy. Adelstein et al.,¹⁴⁴ from the Cleveland Clinic, conducted a study in which 45 patients with stage IIIA or IIIB NSCLC received induction cisplatin, paclitaxel and 30 Gy of accelerated hyperfractionated radiation therapy (1.5-Gy fraction twice daily). Resection was then performed approximately 4 weeks after induction. The overall response rate was 54%. Forty patients (89%) proceeded to operation, and 32 patients (71%) underwent complete resection. Five complete pathologic remissions were seen. Fourteen patients overall were downstaged. Patients received a consolidation dose of chemotherapy and additional radiation to a total of 60 to 63 Gy. The 2-year relapse-free survival rate was 47%, and the 2-year survival rate was 65%. No apparent therapy-related deaths occurred, but the toxicity was high, with 89% of patients experiencing significant mucositis and 20% experiencing esophagitis of grade 3 or worse. Three-dimensional conformal therapy permits higher radiation dosing (> 70 Gy) of the tumor while sparing surrounding normal lung to provide improved local control.^{145,146}

7 The management of stage III NSCLC is complex and still evolving. Many trials indicate that resectability and survival rates are probably improved with the use of combined-modality therapy than with radiation or resection alone. Regimens incorporating high-dose cisplatin with or without moderate-dose radiation have achieved the best results with acceptable levels of toxicity. Careful patient

management leads to complete resection, and the operative risk is comparable with that of standard pulmonary resection. Importantly, combined-modality treatment requires close collaboration among medical oncologists, radiation oncologists, surgeons and pulmonologists, preferably in a multidisciplinary tumor board setting, as well as anesthesiologists at the time of operation. In the future, three key areas warrant further investigation: (a) The optimal combination and sequence of newer, less toxic chemotherapeutic agents and a variety of new radiation techniques; (b) whether concurrent chemoradiation is superior to chemotherapy alone as preoperative induction therapy; and (c) the identification of the molecular features that dictate tumor response to different chemotherapeutic agents allowing a more individualized selection of induction treatment regimens which may lead to improved long-term outcomes.

Superior Sulcus Tumors

Tumors of the superior sulcus (Fig. 79-2), described in detail by H. K. Pancoast in 1932,¹⁴⁷ represent an uncommon (3%) and challenging subset of NSCLC. Tumors frequently involve the brachial plexus, subclavian vessels, or spine and typically fall into two categories; T3N0–1 (stage IIB or IIIA) or T4N0–1 (stage IIIB).¹⁴⁸ Until the 1950s these tumors were felt to be almost universally fatal, with no benefit provided by resection. In 1961, Shaw and Paulson demonstrated that preoperative thoracic radiation followed by resection was potentially curative.¹⁴⁹ For the subsequent 30 to 35 years, reports demonstrated 5-year survival of approximately 25% to 30%. In a single-institutional experience, spanning 24 years, during which 225 patients underwent thoracotomy at MSKCC, 5-year survival for patients undergoing resection for Stage IIB, IIIA and IIIB superior sulcus tumors was 46%, 0% and 13%, respectively.¹⁵⁰ In this retrospective study, the mode of preoperative therapy, with radiation and/or chemotherapy, or adjuvant therapy did not appear to affect survival, which was influenced only by the completeness of resection and tumor (T) and nodal (N) status in a multivariate analysis. As in other retrospective series, locoregional recurrence was the most common form of relapse, occurring in 40% of patients.¹⁵¹

Figure 79-2. Gross figure of a squamous cell carcinoma showing a superior sulcus tumor (Pancoast tumor) arising from apex of the right lung. From Cagle PT. *Color Atlas and Text of Pulmonary Pathology*. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.

Spurred by reports of the apparent success of neoadjuvant chemotherapy and thoracic radiation in achieving improved local control and survival for patients with locoregionally advanced NSCLC, the Southwestern Oncology Group coordinated a phase II trial, the first prospective, multicenter trial (SWOG 9416/Intergroup 0160) for superior sulcus tumors.¹⁵² Of 110 patients eligible, including 32 patients with T4 disease, 104 completed induction chemoradiation and 95 were eligible for operation. Patients with mediastinal lymph node metastases (N2) were excluded from this trial. Of the 88 patients who underwent thoracotomy, 83 had a complete resection, with 61 patients demonstrating complete pathologic response (R0) or minimal residual disease (R1). There were three treatment-related deaths

and two perioperative deaths. Of note, intracranial and other distant metastases were more common (22% each) than locally recurrent disease only (11%). Overall 2- and 5-year survival was 55% and 41% for all patients enrolled, and 70% and 53% for patients with a complete response.

NEUROENDOCRINE TUMORS

Neuroendocrine tumors of the lung include a varied group of lesions ranging from tumors with low-grade malignant potential (typical carcinoid) to SCLC, which is among the most rapidly growing and aggressive of human tumors. Between those two extremes, atypical carcinoid and large cell neuroendocrine carcinoma have been defined.¹⁵³

Figure 79-3. Typical carcinoid tumor of the lung. A microscopic view shows ribbons of tumor cells embedded in a vascular stroma. From Rubin E, Farber JL. *Pathology*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.

Typical and Atypical Carcinoid Tumors

Carcinoid tumors, which are neoplasms with a low-grade malignant potential, account for about 2% of lung tumors in the United States. They arise from neuroendocrine stem cells of the bronchial epithelium and are classified as either typical or atypical. Histologically, typical carcinoids consist of uniform polygonal cells with round nuclei and fine granular chromatin (Fig. 79-3). Mitotic figures are rare. Atypical carcinoids show increased mitotic activity, nuclear pleomorphism, and areas of disorganized architecture and tumor necrosis (Fig. 79-4).¹⁵⁴

Carcinoid tumors occur equally in both sexes and at a median age of 55 years. Half of patients present with pulmonary symptoms, including hemoptysis, dyspnea, and recurrent or persistent pneumonitis because 40% of lesions are centrally located in the main or lobar bronchi (Figs. 79-5 and 79-6). The lesions may be diagnosed by bronchoscopy, appearing as pink or purple friable endobronchial masses covered by intact epithelium. In the other half of patients, carcinoid tumors are diagnosed when radiologic abnormalities are detected on a chest roentgenogram as part of a routine examination.¹⁵⁵

Figure 79-4. Atypical carcinoid tumor of the lung. A cellular tumor shows central necrosis and a disorganized architecture. From Rubin E, Farber JL. *Pathology*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.

Figure 79-5. Gross figure of a carcinoid tumor protruding into the bronchial lumen. From Cagle PT. *Color Atlas and Text of Pulmonary Pathology*. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.

Lymph node metastases occur in approximately 10% to 15% of patients at diagnosis but are more frequent in atypical carcinoids. Carcinoid syndrome is associated with bronchial carcinoids in only 2% of cases, usually in patients with metastatic disease, particularly to the liver. The most common sites of metastases are lung, bone, liver, adrenals, and brain.¹⁵⁵

The standard treatment for bronchial carcinoids is complete resection, regardless of the presence of nodal involvement, with mediastinal lymph node sampling or dissection. Lobectomy can be accomplished in the majority of patients with resectable disease, although parenchymal-sparing segmentectomy or nonanatomic wedge resection can be considered particularly for patients with a typical carcinoid tumor.¹⁵⁶ For patients who have centrally located tumors and for which pneumonectomy might be performed, bronchoplastic techniques (i.e., sleeve lobectomy) should be considered instead.¹⁵⁷ Endoscopic resection is invariably associated with local recurrence and should be used only as a palliative maneuver in patients whose general medical condition precludes thoracotomy and pulmonary resection.¹⁵⁵

Figure 79-6. Gross figure of a resected carcinoid tumor cut in cross section to show invasion through the bronchial cartilage. From Cagle PT. *Color Atlas and Text of Pulmonary Pathology*. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.

The long-term survival rate after resection exceeds 90% in patients with typical carcinoids, even when hilar or mediastinal nodal metastases are present. In contrast, patients with atypical carcinoids have a 5-year survival rate of 60% after complete resection. The outcome is more closely linked to histology than to tumor size, location, or nodal involvement. Recurrence is more frequent with tumors larger than 3

cm and in patients who present with lymph node metastases.^{157,158}

Large Cell Neuroendocrine Carcinomas

Large cell neuroendocrine carcinoma is characterized by the microscopic features of neuroendocrine tumors, but the tumor cells are large, have a high mitotic rate, and frequently show necrosis (Fig. 79-7).^{153,154} According to Travis et al.^{159,160} large cell neuroendocrine carcinomas are related to smoking, as is SCLC, and are high-grade tumors with 5- and 10-year survival rates of 27% and 9%, respectively, despite complete resection. Few data are available concerning adjuvant therapy. For the time being, the management of large cell neuroendocrine carcinoma is identical to that of NSCLC.¹⁶¹

Small Cell Lung Cancer

Small cell carcinoma of the lung has the most aggressive clinical course of any type of pulmonary tumor and is often widely disseminated by the time of diagnosis. The proportion of patients with SCLC has been decreasing from 17% in the 1980s to 13% of lung cancer cases in 2002.¹⁶² In contrast to non-small cell tumors, these lesions are notably responsive to chemotherapy and are rarely within the domain of the surgeon. The staging system for SCLC was developed by the Veterans Administration Lung Cancer Staging Group and divides patients into those with limited-stage (LS) and those with extensive-stage (ES) disease. This distinction was first based on what could be encompassed by a tolerable radiation portal. After clarification by the International Association for the Study of Lung Cancer, LS disease includes patients with tumors confined to one hemithorax and regional lymph nodes (hilar, ipsilateral, and contralateral mediastinal nodes, and ipsilateral and contralateral supraclavicular nodes) as well as patients with ipsilateral pleural effusion, regardless of whether the cytology is positive or negative.¹⁶³ On the other hand, both pericardial and bilateral pulmonary involvement are considered ES disease.¹⁶⁴

Figure 79-7. Large cell neuroendocrine carcinoma of the lung shows positive immunostaining with synaptophysin antibody. From Cagle PT. *Color Atlas and Text of Pulmonary Pathology*. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.

Common sites of distant metastases are bone, liver, bone marrow, and the central nervous system, and therefore the metastatic evaluation includes a bone scan, CT of the chest and abdomen, and brain MRI. Some oncologists also perform bone marrow biopsies, but because the marrow is the sole site of extensive disease in fewer than 5% of patients, biopsies are usually judged unnecessary. After the staging process, approximately 30% to 40% of patients are found to have LS disease.

For patients with LS SCLC, response rates of 85% to 90% and complete response rates of 50% to 60% can be expected with the combination of etoposide and cisplatin and radiation therapy.¹⁶⁵ The median survival is 18 to 24 months, and the 2-year survival rates are 40% to 50%. The addition of definitive-dose thoracic radiation therapy, particularly when administered concurrently or within several weeks of completing chemotherapy confers a 5% 2- to 3-year overall survival benefit.¹⁶⁶⁻¹⁶⁸ In ES SCLC treated with chemotherapy, response rates reach 75% to 85%, although complete response is seen in only 15% to 25% of patients. The median survival is between 7 and 11 months, with a 2-year survival less than 5%.¹⁶² Although the prognosis in SCLC depends primarily on the anatomic extent of disease, after a review of prognostic variables in its 2,580-patient SCLC database, the Southwest Oncology Group determined that the two-stage system should be extended into a four-stage system, with serum lactate dehydrogenase level, age, and pleural effusion used as additional staging criteria.¹⁶⁹

The small numbers of patients with SCLC seen by the surgeon represent fewer than 10% of all patients with SCLC. Such patients have peripheral tumors with no nodal involvement or only hilar nodal involvement, which would be classified as T1–2 N0–1 (stage I or II) tumors in the TNM staging system. In the past, such tumors were often diagnosed at exploratory thoracotomy for an asymptomatic coin lesion, but with the increasing use of diagnostic percutaneous needle aspiration, more patients with early-stage SCLC are now identified preoperatively. Such patients should be evaluated in a multidisciplinary setting in conjunction with medical and radiation oncology, and resection should be considered after distant disease has been excluded. For such potentially operable patients, it has been suggested that the TNM classification be used in future trials and studies.^{170,171}

Retrospective series have demonstrated a 5-year survival rate of 30% to 50% after resection of T1 N0 or T2 N0 SCLC.^{170,172,173} Because of the propensity for small cell cancers to disseminate, adjuvant chemotherapy has traditionally been given to patients although no prospective, randomized trials have demonstrated whether this is of any benefit, due to the small numbers of patients available.¹⁷³ Relapse at the primary site, which is a problem for most patients with LS SCLC, is distinctly uncommon after complete resection of these early tumors.¹⁷⁴ Radiation therapy to the chest has been suggested after complete resection, but because insufficient information is available in the literature, and local relapse is uncommon, this is not considered standard treatment.^{172,173} Given the propensity for patients to develop brain metastases, prophylactic cranial irradiation is recommended for patients with either LS- or ES SCLC with good performance status and who have completed initial therapy with either complete or partial response.¹⁷⁵

As the role of resection in patients with mediastinal nodal involvement (N2 disease) is questionable, mediastinoscopy or EBUS should be considered mandatory to exclude mediastinal nodal disease.¹⁷⁶ This should be performed separately from thoracotomy since it can be difficult for the pathologist to diagnose small cell cancer on a frozen section. The intraoperative management of SCLC is not significantly different from that of NSCLC, and an incomplete resection does not benefit the patient.

The addition of resection after response to induction chemotherapy has been proposed by some surgeons to cure a small number of patients with LS SCLC without mediastinal involvement.¹⁷⁷ To date, the LCSG has performed the only prospective, randomized trial evaluating the role of surgery in LS SCLC.¹⁷⁸ All patients enrolled in this study received induction chemotherapy. Objective responders were randomized either to lung resection followed by thoracic and cranial radiation or to radiation therapy alone. Because the survival rate was the same in both groups, with 2-year overall survival of 20%, this trial did not support the addition of pulmonary resection to the multimodality treatment of SCLC. More recently retrospective studies suggest better long-term survival, in selected patients with stage I SCLC, of over 50% at 5 years.¹⁷¹

Finally, the occurrence of a second primary lung carcinoma after treatment for SCLC has been reported in the few patients with prolonged survival. It should not be assumed that the new tumor is of small cell histology, and these patients should be evaluated for the possibility of resection.¹⁷⁹ The average risk for the development of a second lung cancer in patients who survive SCLC is approximately 6% per patient per year.⁸³

Bronchial Gland Carcinomas

Bronchial gland carcinomas are rare primary tumors of the lung. They constitute about 1% of all lung neoplasms and 2% of the tumors for which resection is performed. These tumors are also called *primary salivary gland-type tumors of the lung* because the tracheal and bronchial airway submucosa and the salivary glands contain serous and mucous glands that are histologically similar.¹⁸⁰ Often, they are called *bronchial adenomas*, but this term is misleading because they are malignant. Care must be taken to separate these primary tumors from metastases of primitive salivary gland tumors.¹⁸¹ This group of carcinomas includes adenoid cystic carcinoma, mucoepidermoid carcinoma, and the even rarer mixed tumor (pleomorphic adenoma). The only truly benign tumors are mucous gland adenomas.

The symptomatology of these tumors is determined essentially by their location and size.¹⁸¹ Peripheral tumors, which are less frequent, are asymptomatic, generally presenting as a nodule on routine chest radiography. Proximally located tumors present with symptoms of bronchial irritation and obstruction, including cough, shortness of breath, hemoptysis, recurrent infection, wheezing, and stridor. Sometimes, patients have constitutional symptoms, such as weight loss and pain. On chest radiography, the nodule may be seen with pneumonia or atelectasis. Because of the slow growth of these tumors, signs and symptoms may develop over a period of years. Incompletely obstructing tumors frequently masquerade as asthma for prolonged periods of time. Smoking does not seem to be a risk

factor for these tumors.

Peripheral tumors are diagnosed by percutaneous needle aspiration biopsy or by wedge resection at the time of operation. Endobronchial tumors are diagnosed by bronchoscopy. Other studies, such as CT, are rarely required to make the diagnosis but may be of value in planning therapy. Because most of these tumors do not metastasize, complete excision, with preservation of as much pulmonary tissue as possible, is the goal. Whenever possible, sleeve resections of main bronchi are performed to preserve pulmonary tissue.

Adenoid Cystic Carcinoma

Adenoid cystic carcinomas are slowly growing malignant tumors that arise from the submucosal glands of the trachea and main bronchi (Fig. 79-8). They have also been called *cylindromas*, *adenoid cystic basal cell carcinomas*, *adenomyoepitheliomas*, and *pseudoadenomatous basal cell carcinomas*. Adenoid cystic carcinomas behave much like the major and minor salivary gland tumors of the same name, to which they are microscopically identical. An important aspect of their clinical behavior is that they tend to spread in the submucosal plane along the perineural lymphatics, well beyond the obvious endoluminal component of the tumor (Fig. 79-9). In a small biopsy specimen, it can be difficult to distinguish adenoid cystic carcinoma from a conventional adenocarcinoma. Immunohistochemical stains may help the pathologist differentiate the two by showing the presence of the myoepithelial cell immunophenotype in adenoid cystic carcinoma.¹⁸¹

Figure 79-8. Tracheogram demonstrating airway obstruction by an adenoid cystic carcinoma of the upper trachea.

Figure 79-9. Adenoid cystic carcinoma. A photomicrograph shows perineural infiltration by the tumor. From Rubin E, Farber JL. *Pathology*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.

Whenever possible, total excision by tracheal resection or tracheobronchial resection is the treatment of choice.^{182–185} This is not always possible because of the extensive submucosal spread of tumor. In such cases, the tumor should be resected with grossly negative margins along with adjuvant radiation since these tumors are radiation-sensitive.

When resection is not feasible because of the extent of the lesion or the functional status of the patient, a palliative treatment option is endoscopic laser removal followed by radiation (brachytherapy, external beam irradiation, or both). When complete resection is possible, the prognosis is excellent. However, because of the slow-growing nature of the tumor and its responsiveness to radiation, prolonged survival is possible even with incomplete resection or palliative measures. Patients frequently live 10 years or more with persistent disease, including pulmonary metastases. In such cases, repeated efforts at palliation are indicated.

Mucoepidermoid Carcinoma

Mucoepidermoid carcinomas may be low- or high-grade malignancies and have the same microscopic appearance as mucoepidermoid tumors of salivary gland origin. These tumors also arise in the glandular submucosa, presenting as submucosal lesions. The distinction between a low-grade and high-grade tumor is based on mitotic activity, cellular necrosis, and nuclear pleomorphism.¹⁸⁰

The principles of treatment of mucoepidermoid tumors are similar to those of carcinoid tumors. The more malignant variety must be treated as a bronchogenic carcinoma. Some authors even think that adenosquamous carcinoma is the same entity as mucoepidermoid carcinoma, but arising in the periphery of the lung.¹⁸⁰ The outlook for these tumors depends on the grade of malignancy and the stage of the disease. High-grade tumors have the same prognosis as bronchogenic carcinoma. Complete resection is the mainstay of treatment. Mucoepidermoid tumors are too rare to permit an evaluation of combined modality therapy for more aggressive, high-grade tumors.¹⁸⁰

Mucous Gland Adenoma

Mucous gland adenomas are rare submucosal tumors that arise from mucous glands. They are also known as *bronchial cysts* and *papillary cystadenomas*. Because of their totally benign behavior, they can usually be treated by endoscopic excision. Thoracotomy and resection are indicated only if the distal lung has been destroyed by chronic infection or if endoscopic removal is technically contraindicated or incomplete.

OTHER MALIGNANT TUMORS OF THE LUNG

The lung is composed of epithelial, mesodermal, and endodermal cells, and malignant tumors may arise from any of these cells. This group represents less than 1% of all primary lung cancers and is usually subdivided into lymphoid tumors, soft-tissue sarcomas, mixed epithelial/mesenchymal tumors, and ectopic tissue tumors.^{186,187} Primary pulmonary lymphomas usually are excised for confirmatory diagnosis. Sarcomas arising from soft tissue or large vessels are treated in a similar fashion to sarcomas occurring elsewhere. Treatment of the other rare tumors, including pulmonary blastomas, primary melanomas of the bronchus, and malignant teratomas, primarily involves complete resection. Radiation and chemotherapy do not have well-defined roles in the treatment of any of these tumors but are occasionally used in particular situations.

RESECTION OF PULMONARY METASTASES

Historical Background

The first report of the resection of a pulmonary metastasis performed as a separate procedure is attributed to Divis in 1926. In North America, the most quoted case of lobectomy for a metastatic carcinoma was that performed by Barney and Churchill in 1939.¹⁸⁸ Their patient underwent nephrectomy for an adenocarcinoma and was known to have a pulmonary mass. After the renal resection, the pulmonary tumor did not respond to radiation treatment and increased in size. Following

exploration and resection of the pulmonary lesion, the patient survived disease-free for more than 20 years.

From 1940 to the mid-1960s, pulmonary metastasectomy was performed infrequently and only in highly selected patients. A total of 169 pulmonary metastasis resections were performed on 165 patients at the Mayo Clinic from 1941 to 1959.¹⁸⁹ This large number of operations may reflect the high volume of cases seen at the Mayo Clinic rather than the common use of resection at that time. The first principles of pulmonary resection for metastatic disease included complete removal of the primary disease, no evidence of recurrent or metastatic disease other than the lung lesion, and that the patient was in good general condition. Multiple lesions were not considered a contraindication to resection (Fig. 79-10), but it was thought that bilateral disease indicated a poor prognosis and should not be resected. Surgeons were already convinced that the resection should be as conservative of lung function as possible.

Since then, experience from several institutions suggested that more liberal indications for pulmonary metastasectomy are appropriate.¹⁹⁰ A striking example was the treatment of metastatic osteogenic sarcoma at Memorial Sloan-Kettering Cancer Center. From 1940 to 1965, only five such patients were treated surgically. During the same period, only 24 of 145 patients (17%) survived 5 years after resection of their primary tumors, and 118 of these patients (81%) died of pulmonary metastases. This experience prompted a more aggressive approach to the management of pulmonary metastases. Starting in 1965, a consecutive series of 22 patients with osteogenic sarcoma underwent pulmonary metastasectomy. Patients were considered for operation even if they had bilateral metastases or required multiple thoracotomies to remove all gross tumor. A total of 59 thoracotomies were performed in these 22 patients, with an overall 5-year survival rate of 32%. The dramatic improvement in survival in comparison with the historical experience strongly supported the aggressive use of pulmonary metastasectomy in these patients.¹⁹¹

Figure 79-10. Metastatic carcinoma of the lung. A section through the lung shows numerous nodules of metastatic carcinoma, corresponding to “cannon ball” metastases seen radiologically. From Rubin E, Farber JL. *Pathology*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.

During the past 30 years, resection has become a widely accepted treatment for certain pulmonary metastases; however, some of the criteria for patient selection remain controversial. In addition, advances in chemotherapy have changed the indications for resection. With some cancers, pulmonary metastasectomy is performed to prolong life expectancy, whereas with others, it serves mainly to restage disease or to provide adjuvant treatment after initial chemotherapy. The role of pulmonary metastasectomy will undoubtedly continue to evolve as improvements in systemic treatment are made.

Clinical Presentation and Diagnosis

Metastases are asymptomatic 85% of the time and are usually detected on a routine chest radiograph. Patients who undergo resection of a primary tumor with a known tendency to metastasize to the lung should have a chest radiograph as part of their routine follow-up care. On chest radiograph, metastases usually present as well-circumscribed, spherical solid masses with well-defined borders (Fig. 79-11). Cavitation is occasionally seen in large lesions with central necrosis, mostly squamous cell cancers. The distribution of lung metastases is predominantly subpleural or in the outer-third of lung fields.¹⁹²

Metastases to the lung usually arise in the pulmonary parenchyma. Endobronchial metastases are uncommon but occur most typically with renal cell, colon, and breast cancers. Even with endobronchial metastases, half of patients are asymptomatic.¹⁹³ More often, endobronchial disease represents an extension of contiguous parenchymal disease. The extent of endobronchial tumor can affect the approach to resection. For these reasons, bronchoscopy should be performed before thoracotomy, especially if centrally located metastases are present.

Figure 79-11. Chest radiograph of a patient with bilateral pulmonary metastases from endometrial cancer. The mass in the right upper lobe is well circumscribed and has the radiographic appearance typical of a metastasis.

Hilar or mediastinal nodal involvement sometimes accompanies pulmonary metastases. Several retrospective series have indicated that metastatic nodal involvement is a poor prognostic indicator, independent of disease-free interval or number of nodules.^{194,195} However, the determinants of nodal involvement and the prognostic and therapeutic implications remain poorly understood. Lymphangitic spread can occur with or without concomitant pulmonary nodules. This happens most frequently in breast cancer and produces a characteristic radiographic appearance of diffusely increased interstitial markings and a clinical presentation of severe dyspnea that is out of proportion to the radiographic findings.

When pulmonary metastases are thought to be present on a chest radiograph, CT should be performed to determine their number, location, size, and potential resectability. Plain chest radiographs detect only lesions at least 9 mm in size. New lesions of this size seen on a chest radiograph in a patient already treated for a malignancy have a 90% chance of being malignant.¹⁹⁶ Even though CT can identify lesions as small as 3 mm, it often underestimates the number of pulmonary metastases (Fig. 79-12). When radiologic and surgical findings are correlated, only 75% of malignant nodules are detected by CT. Fifteen percent of CT studies overestimate the number of lung metastases for an accurate radiologic assessment of 61%.^{197,198} FDG-PET scan appears to have a role as well in the preoperative evaluation of resectable pulmonary metastases, enhancing the detection of extrathoracic or mediastinal involvement that might preclude complete resection.¹⁹⁹

8 Patients who present with multiple pulmonary nodules in the setting of a previously treated malignancy rarely pose a diagnostic dilemma. Patients who present with solitary pulmonary nodules are more problematic. Generally, a solitary lesion is more likely to be a metastasis if the primary tumor was a sarcoma or a melanoma. If the primary tumor originated in the head, neck, or breast, it is more likely to be a new primary lung cancer.²⁰⁰ It has an equal chance of being a metastasis or a new primary if the initial tumor was of gastrointestinal or genitourinary origin. Percutaneous fine-needle aspiration biopsy usually yields a tissue diagnosis, but the necessity of a biopsy in the case of a solitary lesion is questionable. If the patient fits the criteria for resection, a biopsy of the lesion is best performed as an

excisional biopsy. Because the findings on needle biopsy do not alter the recommendations for excision of a solitary lesion, this procedure should be undertaken only if the patient is not an operative candidate, if an alternative method of treatment is indicated, or if the patient requests that the diagnosis be established before consenting to operation.

Figure 79-12. Imaging studies from a patient with metastatic embryonal rhabdomyosarcoma. Chest radiographs show a mass in the right lower lobe (*arrow*, A) that is best seen on the lateral view (*arrow*, B). Computed tomography (CT) confirmed the presence of this mass (*arrow*, C) and showed an additional nodule in the left upper lobe (*arrow*, D). At surgical exploration, however, multiple bilateral pulmonary metastases were found that measured less than 5 mm and therefore were not seen on CT.

Criteria for Resection

The disease-free interval, number of metastatic nodules and tumor doubling time all have been used as criteria for the resection of pulmonary metastases. Each of these remains controversial with respect to its effect on long-term outcome.²⁰¹ The disease-free interval is defined as the time from resection of the primary tumor to the diagnosis of metastases. The length of the disease-free interval is thought to be of prognostic significance and varies greatly among published reports from 7 months to 5 years.²⁰²

The number of metastatic nodules resected has also been considered predictive of survival. In sarcomas, some have reported that the presence of four nodules is a significant breakpoint in survival; however, the significance of the number of nodules varies among reported series. Most consider the completeness of resection the best predictor of survival.²⁰³ Obviously, when a shower of numerous, tiny (1 to 2 mm) lesions is encountered, complete resection is not possible.

Tumor doubling time is a measure of the aggressiveness of tumor growth. The prognostic importance of tumor doubling time, however, is questioned because various doubling times, from 20 to 136 days, have been found to be significant in different studies.²⁰² Many do not consider this a criterion for resection. The disease-free interval, number of metastatic nodules, and tumor doubling time in fact reflect the intrinsic tumor biology.

In 1991, the International Registry of Lung Metastases was established. Five thousand two hundred six cases of pulmonary metastases were analyzed retrospectively with regard to prognostic variables.¹⁹⁷ Multivariate analysis showed a better prognosis for patients with germ cell tumors, a disease-free interval of 36 months or more, a single metastasis, and complete resection. A simple system of classification into prognostic groups was designed (Table 79-11).

Several guidelines must be met before a patient is considered for resection of pulmonary metastases: (a) control of the primary tumor, (b) absence of extrathoracic metastases, (c) a general medical condition that permits thoracotomy or thoracoscopy, (d) pulmonary function that allows complete resection of all metastases, and (e) lack of a more effective systemic treatment. Resection should be undertaken only if complete resection is considered technically feasible.²⁰⁴

RESULTS

Table 79-11 Survival by Prognostic Group: The International Registry of Lung Metastases

Groups	Median Survival (mo)	
I	Resectable, no risk factors (DFI $\geq$ 36 mo and single metastasis)	61
II	Resectable, 1 risk factor (DFI <36 mo and multiple metastases)	34
III	Resectable, 2 risk factors (DFI <36 mo and multiple metastases)	24
IV	Unresectable	14

DFI, disease-free interval.
From Pastorino U, Buyse M, Friendel G, et al. Long-term results of lung metastasectomy: prognostic analyses based on 5,206 cases. *J. Thorac Cardiovasc Surg* 1997;113:37–49.

If the metastatic lesion is found at the same time as a recurrence at the primary site, the recurrent primary tumor should be treated before the metastatic disease is resected to prevent further tumor seeding. When the primary tumor and the metastasis are diagnosed simultaneously, lung resection may precede operation for the primary disease if it is doubtful whether the pulmonary disease can be completely resected, and immediate subsequent resection of the primary tumor is planned.

When a patient meets the criteria for resection of one or more pulmonary metastases, the natural history of the tumor and whether effective systemic therapy is available must be considered. Experience in breast cancer, testicular cancer, and osteogenic sarcoma illustrate this point.²⁰⁵ In contrast to metastatic sarcoma, which is usually confined to the lungs, metastatic breast cancer to the lungs signals the development of widely disseminated disease. Although effective systemic therapy is available, patients with a solitary metastatic lesion, long disease-free interval following treatment for the primary breast cancer and good performance status appear to have longer median and 5-year survival following pulmonary resection.^{206,207}

The advent of effective chemotherapy has altered the management of pulmonary metastases of germ cell cancer and rendered an incurable disease curable. Platinum-based chemotherapy is now the primary form of treatment.²⁰⁸ Resection is reserved for patients who have a complete serologic response (normal levels of β -human chorionic gonadotropin and α -fetoprotein) with residual pulmonary lesions, evidence of persistent intrathoracic disease with elevated markers despite a full course of chemotherapy, or lesions that do not respond or that progress with chemotherapy.²⁰⁹ Approximately one-third of the resected pulmonary lesions contain viable tumor, one-third contain fibrosis or necrosis, and one-third are teratomas. A teratoma is removed to prevent it from degenerating to a more malignant form of germ cell tumor and to avoid the potential complications of local tumor growth. Residual tumors are found mostly in patients with positive serology, and the prognosis is usually not as good as when no residual disease is present.²¹⁰ In addition, the presence of residual pulmonary disease, as opposed to mediastinal disease, appears to portend a worse survival. Patients who are fit for operation can derive significant long-term survival even though thoracic metastasectomy has a strictly adjuvant role in the treatment of malignant germ cell tumors.²¹¹

The development of more effective chemotherapy regimens for sarcomas, especially osteogenic sarcomas, has also altered the management of pulmonary metastases in this disease. Resection is part of a multimodality treatment approach, but the manner in which chemotherapy and resection should be combined is less clear than in germ cell cancer. The timing of an operation in relation to chemotherapy

depends on the number, size, and location of pulmonary metastases at diagnosis and on whether the patient has received any previous chemotherapy. Often, resection is performed between cycles of chemotherapy, with the aim of controlling both gross and micrometastatic disease. This approach allows the sensitivity of the patient's tumor to chemotherapy to be assessed, and the advisability of continuing the regimen postoperatively can be determined. The thoracic surgeon should collaborate with the medical and radiation oncologists in planning a multidisciplinary treatment program for patients with pulmonary metastases from sarcoma.

Preoperative Evaluation

The preoperative evaluation of the patient undergoing resection of pulmonary metastases is similar to that of the patient undergoing removal of a primary lung cancer. Tests including pulmonary function, arterial blood gases, and, if necessary, ventilation–perfusion lung scanning are performed to be sure that the patient has sufficient reserve to tolerate complete resection of the metastases. The pulmonary function of patients who received chemotherapy may be substantially reduced. This is particularly true of patients treated with bleomycin and mitomycin, which can markedly diminish the diffusion capacity and, occasionally and unpredictably, cause an acute respiratory distress type of syndrome postoperatively. Maintaining patients on 35% or less inspired oxygen intraoperatively is thought to help prevent this complication. Like patients with primary lung cancers, these patients should stop smoking. Patients who smoke actively up to the time of operation are at risk for postoperative atelectasis or pneumonia.

It is also important to assess the patient's general medical condition and cardiovascular status. Older patients may have underlying coronary artery disease that requires preoperative treatment and additional perioperative monitoring. The cardiac function of patients who previously received chemotherapy, especially doxorubicin, may be impaired. A preoperative radionuclide scan or echocardiogram should be performed to determine the left ventricular ejection fraction and assess whether intraoperative hemodynamic monitoring is necessary. Other drugs, such as cisplatin, can impair renal or neurologic function and may influence perioperative management.

If a patient has recently undergone chemotherapy, the timing of surgery should be planned after consultation with the medical oncologist, so that the operation is not performed when the patient is neutropenic or thrombocytopenic. Resumption of chemotherapy postoperatively should also be a joint decision between the surgeon and medical oncologist so that it does not compromise wound healing.

Surgical Technique

Two principles guide the approach to resecting pulmonary metastatic lesions; complete resection of disease and maximal sparing of functioning lung tissue. Wedge resections should be performed whenever possible. A lobectomy or even a pneumonectomy may be performed when wedge resection will not provide a complete resection. This may be necessary for recurrences (completion pneumonectomy), centrally located tumors, or multiple metastases.^{212,213}

Unilateral disease is approached by a standard anterolateral or posterolateral thoracotomy incision. Patients with bilateral pulmonary metastases should have a simultaneous resection of the bilateral lesions if technically feasible. This can be accomplished by a median sternotomy or a clamshell incision (bilateral anterior thoracotomy with or without transverse sternotomy). A clamshell incision provides better exposure to the posterior aspects of the lungs, particularly the left lower lobe, which is difficult to access by a median sternotomy.²¹⁴ Bilateral pulmonary nodules may require sequential posterolateral thoracotomies if they are centrally located and good exposure of the hilar vessels is needed.

The role of VATS in the management of patients with isolated suspected pulmonary metastasis is clear when performed for diagnostic purposes. VATS wedge resection can be carried out with a high degree of success and minimal morbidity.²¹⁵ Although the use of thoracoscopy in the resection of pulmonary metastases is increasing, its use remains controversial. In a series of 318 patients reported by Petersen et al. undergoing resection of metastatic melanoma, 40 patients underwent thoracoscopic resection.²¹⁶ According to the authors, thoracoscopy has been their preferred approach to metastasectomy in the past few years utilizing chest CT for preoperative localization and ring clamp or digital palpation for intraoperative confirmation.

Gossot et al. compared 31 patients undergoing thoracoscopic resection to 29 patients undergoing thoracotomy for resection of metastatic sarcoma.²¹⁷ They found no significant difference in 1-, 3-, or 5-year survival. There was also no significant difference in disease-free survival. They recommend a minimally invasive approach for patients with less than two pulmonary nodules that are both amenable

to wedge resection with no mediastinal or chest wall invasion. Thoracoscopic resection may also be beneficial in terms of causing fewer adhesions as Briccoli et al. have shown that 35% of patients undergoing metastasectomy for sarcoma will require a repeat resection resulting in acceptable survival rates as long as pulmonary function is maintained.²¹⁸

Table 79-12 Histologic Subtypes from the International Registry of Lung Metastases

Histologic Groups	No. of Patients (%)	Subtypes
Carcinoma	2,260 (47)	Breast
		Lung
		Bowel
		Kidney
		Uterus
Sarcoma	2,173 (45)	Head and neck
		Osteosarcoma
		Other bone sarcomas
		Histiocytoma
		Leiomyosarcoma
		Synovial sarcoma
Other types	328 (8)	Other soft tissue sarcoma
		Wilms tumor
		Teratoma
		Embryonal carcinoma
		Other germ cell tumor
		Melanoma

Results

Resection remains the mainstay of treatment for pulmonary metastases from solid tumors that cannot be treated effectively with chemotherapy, including melanoma, colon, renal cell, sarcoma, head and neck, and endometrial cancers. The histologic subtypes of the pulmonary metastases in the International Registry of Lung Metastases are listed in Table 79-12.¹⁹⁷

Globally, the actuarial survival after complete metastasectomy is 36% at 5 years and 26% at 10 years (median survival of 35 months).¹⁹⁷ The experience at Memorial Sloan-Kettering Cancer Center in the resection of pulmonary metastases from renal cell carcinoma, head and neck tumors, colorectal cancers, testicular germ cell tumors, and soft-tissue sarcoma are summarized (Table 79-13). These results again demonstrate that complete resection of metastatic disease is associated with prolonged survival in carefully selected patients. Furthermore, patients who are persistently free of disease at the primary tumor location but who have recurrent resectable metastatic disease of the lung also benefit from repeated surgery.²¹⁹ Mortality rates of pulmonary metastasectomy do not differ from those of thoracic surgery performed for lung cancers, varying between 0.6% and 2%.^{190,209,220} The surgical removal of pulmonary metastases is widely accepted, but its role has changed as more effective chemotherapy has become available for some cancers. It is important that the surgeon understand the indications for operation, the potential side effects of initial chemotherapy, and the ways in which resection should be integrated into the overall treatment plan for these patients.

RESULTS

Table 79-13 Results of Pulmonary Resections for Metastases at Memorial Sloan-Kettering Cancer Center

	No. of Patients	Survival (5 yrs, %)
Renal cell carcinoma (1980–1993) ²²⁴		
Solitary metastasis	50	54
Head and neck cancer (1966–1995) ²²⁰		
Squamous cell	41	34
Glandular tumors	36	64
Overall	83	50
Colorectal cancer (1965–1988) ²²⁵		
Overall	144	44
Soft-tissue sarcoma ^a (1982–1997) ²²⁶		
Complete resection	161	46
Incomplete resection	52	23
No resection	473	17
Unknown	33	
Overall	719	25
Testicular germ cell tumors (1967–1995) ²⁰⁹		
(1967–1974)	22	41
(1975–1984)	69	65
(1984–1995)	66	82
Overall	157	68

^aSurvival at 3 years.

BENIGN TUMORS OF THE LUNG

Benign tumors of the lung are rare neoplasms. Few series are found in the literature, but in a 10-year surgical review (1958 to 1968) from the Mayo Clinic, 130 patients were found to have benign tumors.²²¹ Like malignant tumors, benign tumors arising from epithelial, mesodermal, or endodermal cell lines can develop in the lung. They may present as endobronchial lesions but are more commonly peripheral nodules.²²² Endobronchial tumors present with signs and symptoms related to airway obstruction or bleeding. Tumors arising in peripheral airways or within pulmonary parenchyma usually present as asymptomatic solitary pulmonary nodules. Types of benign lung tumors are listed in [Table 79-4](#).

Hamartoma

The most frequent benign tumors are hamartomas, which represent 75% of benign lesions. They show a predilection for men.²²³ A hamartoma consists of an abnormal arrangement of normal cells. In the lung, the most frequent component is cartilage. A hamartoma usually presents as a solitary pulmonary nodule with an extremely slow growth pattern. Classically, the radiographic appearance is that of a well-circumscribed nodule that may contain popcorn calcification. If previous chest radiographs are available, these tumors are found to have been present for many years. Their growth pattern is variable but generally slow. These lesions can be diagnosed by CT if appropriate calcification is demonstrated. Needle aspiration is frequently diagnostic of a cartilaginous benign lesion.

CLASSIFICATION

Table 79-14 Benign Tumors of the Lung

Epithelial
Polyps
Papilloma
Mucous gland adenoma
Mesenchymal
Vessel
Sclerosing hemangioma
Lymphangioma
Nerve
Granular cell tumor
Neurilemoma
Neurofibroma
Muscle
Leiomyoma
Miscellaneous
Hamartoma
Teratoma
Clear cell (sugar) tumor
Others
Lipoma
Chondroma
Fibroma
Inflammatory Pseudotumors
Plasma cell granuloma
Pulmonary hyalinizing granuloma

Controversy exists regarding whether these lesions should be excised for pathologic diagnosis. Certainly, they do not require excision unless they are proximally located and cause symptoms related to endobronchial obstruction or when carcinoma cannot be ruled out. If transthoracic needle aspiration biopsy confirms the presence of a hamartoma, many surgeons elect to follow patients with annual chest radiography rather than surgical excision. Occasionally, significant growth during follow-up necessitates excision.

Other Benign Tumors

Other benign tumors may present as endobronchial lesions (commonly fibromas, lipomas, chondromas and granular cell myoblastomas). These tumors may be removed endoscopically but frequently require excision when the diagnosis is in doubt or if endoscopic excision has been incomplete. Peripheral tumors often are removed for diagnosis.

Chapter 80

Non-Neoplastic Thoracic Disease

Rishindra M. Reddy

Key Points

- 1 Surgical intervention for chest wall tumors depends on the type of lesion and goals of surgery (resection vs. diagnosis). Reconstruction varies depending on the size of the defect and location on the chest wall.
 - 2 Thoracic outlet syndrome (TOS) may be arterial, venous, or neurogenic. Neurogenic TOS is the most difficult to diagnose and surgery for this should be performed in high-volume centers.
 - 3 The primary treatment for a lung abscess is antibiotic therapy.
 - 4 Hemoptysis can be life-threatening from suffocation due to a low volume of blood in the lungs, not from blood volume loss requiring transfusion.
 - 5 Primary spontaneous pneumothoraces will recur in only 30% of patients after initial treatment. When they recur, the treatment should include a thoracoscopic evaluation and possible pleurodesis.
 - 6 Transudative pleural effusions should be treated medically, while exudative effusions may need more intervention. One-quarter of pleural effusions in a community hospital are due to malignancy.
 - 7 Empyema is a part of a spectrum of disease that may be treated early on with drainage alone, but may require debridement and decortication in more advanced cases.
 - 8 Complications of tracheostomies are usually due to improper placement of the tracheostomy on the trachea (below the 3rd ring, risking a tracheoinnominate fistula) or to the use of high pressures in the cuff of the tracheostomy (causing ischemia and long-term stenosis)
 - 9 Mediastinitis is life-threatening and warrants immediate evaluation, antibiotic therapy, and surgical drainage.
-

INTRODUCTION

This chapter is meant as resource for the general surgery community and surgery residents with regard to pathology in the chest. We will cover a wide variety of topics including most noncardiac congenital disease processes in the thorax.

CHEST WALL ANATOMY

The chest wall is the musculoskeletal structure that contains and protects the structures of the upper trunk or thorax. There are two openings to the thorax, the superior aperture, or the thoracic inlet, and the inferior aperture which leads to the abdominal cavity. The head and arms connect to the intrathoracic structures via the inlet, whereas the diaphragm separates the thoracic and abdominal cavities at the inferior aperture. The inferior vena cava, esophagus, and aorta all travel to the abdomen through the diaphragm at levels T8, T10, and T12, respectively.

The sternum, commonly known as the breast bone, is comprised of three parts, the manubrium, the body, and the xiphoid. The manubrium attaches to the clavicles and the first costal cartilages. The sternal angle where the manubrium and body connect is called the angle of Louis and is an important landmark. The second ribs attach to the sternum at this angle and they allow one to count the ribs from this point down, as the first ribs are not palpable. The body of the sternum contains articular facets for ribs 2 to 7 and connects to the cartilaginous xiphoid inferiorly. The xiphoid may be bifid and will eventually ossify in older adults ([Fig. 80-1](#)).

The ribs are split into two groups; the upper 7 pairs are the true ribs, with articulations to the sternum, while the lower 5 pairs are the false ribs. Ribs 8, 9, and 10 connect to each other and the

upper ribs via their costal cartilage. Ribs 11 and 12 are called floating ribs as they have no anterior connection. Rib 1 is unique in its shape as it is flat, short, and extremely curved. Ribs 2 through 10 have a more standard configuration with the head containing articular facets for the vertebrae. After the neck the tubercle contains the facet for the vertebral transverse process. The costal groove along the inferior portion of the shaft houses the intercostal bundle, consisting of the nerve, artery, and vein (Fig. 80-2). Because of this inferior placement, most chest wall procedures such as thoracostomy tube placement or thoracentesis should be aimed at the superior aspect of the rib to avoid injury to this bundle.

There are three intercostal muscles, the external intercostal, the internal intercostal, and the innermost intercostal muscle. The intercostal bundle lays just external to the innermost intercostal layer (Fig. 80-3). On the inner aspect of the chest wall, the internal thoracic (mammary) artery and vein runs between the innermost intercostal muscle and the transversus thoracis muscles which connect the ribs to the lower half of the sternal body. The intercostal arteries have two sources, one posterior and one anterior. Almost all the posterior arteries arise from the descending thoracic aorta, while the anterior arteries branch off the internal thoracic artery. The intercostal nerve is a branch off the ventral ramus after it joins the sympathetic trunk. The intercostal veins follow the arteries and posteriorly drain into the azygos and hemiazygos veins. Lymphatic drainage from the posterior chest wall drains into the thoracic duct on the left and into the right lymphatic duct on the right.

Figure 80-1. Skeletal support of the thorax. Anterior (A), and lateral (B), views. Note the anterior cartilaginous component of the upper 10 ribs, the fused costal cartilages of ribs 7 through 10, the location of the sternomanubrial junction (angle of Louis) at the level of the second rib, and the oblique course of the ribs laterally from posterior to anterior.

The muscles of the chest wall can be divided embryologically into those from the epimeres, such as the deep back muscles, innervated by the dorsal rami, and those from the hypomeres, such as the intercostals and rectus, innervated by the ventral rami. The musculature can also be classified based on respiratory function, where the primary muscles of respiration are the intercostals and the diaphragm, and the secondary, or accessory muscles are the sternocleidomastoid, scalenes, pectoralis, serratus, and abdominal wall musculature. The major back muscles include the trapezius and latissimus dorsi (Fig. 80-4). In normal breathing, the diaphragm performs a majority of the work with the intercostals supplying about a quarter of the workload. In full inspiration, the pleura extend bilaterally down to the level of the 11th and 12th ribs (Fig. 80-5).

Figure 80-2. Anatomy of ribs 2 to 10 as viewed from above (A), and below (B).

Figure 80-3. Anatomy of the intercostal space. The major intercostal muscles are the external and internal. The neurovascular bundle courses in the costal groove along the inferior aspect of the rib.

Figure 80-4. Thoracic musculature. Anterior (A), and posterior (B), views.

Figure 80-5. Topographic relations of the pleura to the chest wall. Laterally, the pleura extends to the level of the 11th to 12th ribs. The anterior reflection of the mediastinal and costal pleurae forms the costomediastinal recess, whereas the reflections of the costal and diaphragmatic pleurae form the costodiaphragmatic recess.

CHEST WALL NEOPLASMS

Chest wall tumors are very rare. Lesions may be divided into benign and malignant, and then further subdivided into soft tissue versus bony/cartilaginous tumors ([Table 80-1](#)). Most malignant tumors of the chest wall are either metastatic from carcinomas or sarcomas arising in other sites of the body, or from local extension of lung cancers or breast cancers.¹

Almost all lesions will present as a mass, as pain, or as a combination of both. Occasionally they will be asymptomatic and be identified on imaging for cancer surveillance or other reasons.² Fever can occasionally be a presenting symptom in the setting of a systemic neoplastic process. Evaluation of these lesions includes a thorough history and physical and appropriate imaging, which may begin with plain radiographs, but should include three-dimensional imaging such as a CT scan and/or MRI. This will allow for evaluation of the depth of the lesion, the relationship of the lesion to nerve and vascular structures, and the pulmonary fields for possible metastases. Depending on the situation, PET scans may also be useful.¹ Prior films may help ascertain the rate of growth of the lesion.³

Surgical intervention depends on the type of lesion and the goal of surgery. Tumors that are suspected metastases may require only a needle or an incisional biopsy to confirm the diagnosis. Lesions that are possible primary tumors, whether benign or malignant, require excisional biopsies. Some low-grade malignant tumors may be underdiagnosed and considered benign if the entire specimen is not removed and examined. If a tumor is proven to be a primary malignant lesion, wide excision is required, with margins upto 4 cm.³

BENIGN SOFT TISSUE TUMORS

These tumors include lipomas, fibromas, hemangiomas, and neurofibromas among others. These can be removed by excisional biopsy and require no further treatment unless they recur. Inflammatory osteomyelitis can mimic tumors by causing pain.

Table 80-1 Chest Wall Tumor Classification

- Benign tumors
 - Soft tissue tumors
 - Lipomas
 - Fibromas
 - Hemangiomas
 - Neurofibromas
 - Granulomas
 - Inflammatory tumor
 - Tuberculoma
 - Bony/cartilaginous tumors
 - Osteochondromas
 - Chondromas
 - Fibrous dysplasia
 - Eosinophilic granuloma
 - Osteoid osteomas
 - Osteomyelitis
 - Chondro/osteoblastomas
- Malignant tumors
 - Soft tissue tumors
 - Melanomas and other cutaneous cancers
 - Sarcomas
 - Desmoid tumors/low-grade fibrosarcomas
 - Lymphoma
 - Malignant fibrous histiocytoma
 - Bony/cartilaginous tumors
 - Chondrosarcomas
 - Osteogenic sarcomas
 - Ewing sarcomas
 - Solitary plasmacytoma
 - Lymphoma
- Metastatic tumors
 - Breast cancer
 - Lung cancer
 - Mediastinal tumors
 - Mesothelioma
 - Other sarcomas or carcinomas

Figure 80-6. Osteochondroma of left second rib. The stippled calcification within the tumor and the intact cortex of the rib are characteristic.

BENIGN BONY/CARTILAGINOUS TUMORS

About two-thirds of benign chest wall tumors are either osteochondromas, chondromas, or fibrous dysplasia, with osteochondromas comprising almost 50% of all nonmalignant rib tumors. Osteochondromas usually present as painless masses with a male-to-female predominance of 3:1. If the lesion becomes painful it may indicate malignant degeneration.³ They are often found on routine radiographic examinations for other reasons and have a characteristic appearance of a pedunculated

bony prominence (Fig. 80-6).

Chondromas account for 15% of benign rib lesions and grow from the cartilage at the sternocostal junction.¹ They have an equal male-to-female incidence. Clinically and radiographically, it is impossible to distinguish chondromas from chondrosarcomas. It can be difficult microscopically to distinguish chondromas from low-grade chondrosarcomas as well. As a result, all chondromas must be treated as if they are potentially malignant and require complete excision.³

Fibrous dysplasia arises in the lateral portion or shaft of the rib and can have a “soap bubble” or “ground-glass” appearance on radiographs (Fig. 80-7). These lesions may become painful if they enlarge and can result in rib fractures. Surgical excision is needed for diagnosis and symptom relief.⁴ Eosinophilic granulomas and osteoid osteomas are rare conditions that affect men more often. Patients may have multiple granulomas, including the skull and may benefit from radiotherapy as opposed to surgical resection. Osteomas may be symptomatic and if so, should be resected.

MALIGNANT SOFT TISSUE TUMORS

These lesions can range from melanomas to desmoid tumors to malignant fibrous histiocytoomas (MFHs). Sarcomas also arise in the soft tissue of the chest wall, but they comprise less than 10% of all sarcomas.² Desmoid tumors are borderline lesions between a benign and malignant classification, and are sometimes considered low-grade fibrosarcomas.¹ Almost half of all desmoids occur in the chest wall and shoulder where they can encapsulate the brachial plexus. They require wide local excision and have a high rate of recurrence. If they encircle vital structures, they can be treated with radiotherapy after surgical excision.³

Figure 80-7. Fibrous dysplasia of the rib. Note the characteristic expansion and thinning of the cortex (*arrows*) and the central ground-glass appearance.

MFHs are the most common primary chest wall tumors. They are more frequent in men (2:1 ratio) and generally occur after the age of 50. They are slow-growing, painless, and spread along the fascial planes or between muscle fibers. MFHs are unresponsive to other forms of therapy and require wide local excision. Because of the lesion's propensity for fascial plane infiltration, there is a high rate of recurrence following resection and patients who have undergone resection have a 5-year survival of under 40%.³ Rhabdomyosarcoma is the second most common soft tissue lesion of the chest wall and usually occurs in children and younger adults. It grows rapidly from the striated muscle, but is usually painless. It is treated with wide excision followed by radiation and chemotherapy with a reported 70% survival at 5 years.³ A recent review of soft tissue sarcomas in the chest wall suggested that tumor size greater or less than 5 cm correlates with overall prognosis. Also, low-grade tumors had a 100% 5-year

survival rate versus a 69.2% survival in high-grade tumors. There was a trend toward improved survival in patients who received a complete resection versus those left with residual disease, but it did not achieve statistical significance due to small sample size.²

MALIGNANT BONY/ CARTILAGINOUS TUMORS

Chondrosarcomas are the most common primary malignant bony tumors, accounting for 20% to 30% of lesions. These are well-differentiated tumors and on microscopic examination may be difficult to distinguish from their benign counterparts. Local recurrence can occur after excision and if untreated, distant metastases can develop.³ Osteogenic sarcomas are more common in the limbs, but also occur in the ribs. Radiographs depict a characteristic “sunburst” pattern. These tend to grow quickly and often have metastases at the time of initial presentation. Patient evaluation should include a CT scan and bone scan to check for the presence of metastatic disease. Surgery with adjuvant chemotherapy is the treatment of choice for local disease.⁵ Ewing sarcomas constitute 5% to 10% of chest wall tumors. They occur in children and younger adults with a male-to-female ratio of 1.6:1. Symptoms include pain, fever, and fatigue. Radiographs show a large soft tissue mass with bony destruction. Patients often present with metastatic disease, and ultimately three-quarters of patients will develop metastases. Multimodality treatment is the key to treatment. Survival may be less than 30% at 5 years in patients with metastatic disease.⁶

Figure 80-8. Plasmacytoma of the left seventh rib, showing characteristic cortical destruction and relatively large soft tissue component projecting into the chest.

Solitary plasmacytoma is a rare tumor of the plasma cells and can be part of a systemic disease in multiple myeloma. Lesions can be painful and usually occur in men over the age of 50. X-ray findings show cortical destruction of the rib (Fig. 80-8). In the setting of systemic disease, only a needle biopsy may be needed, but if the lesion is small and symptomatic, resection can be offered. For larger lesions, radiotherapy is the primary treatment.¹

METASTATIC TUMORS

As discussed before, metastatic lesions can arise from a variety of other cancers, and treatment depends on the primary histology, time to recurrence, and goals of intervention. For isolated metastases with a long interval before recurrence, surgical resection may be warranted. Each case should be individualized and discussed within a multidisciplinary team.

CHEST WALL RECONSTRUCTION

1 Chest wall defects can result from cancer, radiation, trauma, or infection.⁷ The goals of repair are to protect the thoracic cavity, minimize complications of respiration due to a flail chest, and to provide cosmetic coverage as needed. Surgical repair involves chest wall stabilization and soft tissue coverage. Stabilization depends on the size and the location of the defect. Often, if the defect is small enough, no

stabilization is needed. In larger defects, or when the patient has an intrinsic lung disease limiting their ability to breathe, stabilization using prosthetic materials is warranted. Soft tissue coverage of the defect can vary from mobilization of soft tissue edges, to muscle/omental pedicled flaps, to free muscle flaps.⁸

Size and location generally determine the need for chest wall stabilization. Defects less than 5 cm anywhere in the chest wall, or defects less than 10 cm in the posterior chest wall that are anterior to the scapula do not usually need stabilization.^{7,9} An alternative criteria is to use the number of ribs resected, and to avoid stabilization when a portion of three ribs or less have been removed.¹⁰ Techniques for closure of the defect include utilizing absorbable vicryl mesh, used in the setting of infection or if small defects are present. This approach does not provide any stabilization. More definitive repairs utilize polytetrafluoroethylene (PTFE) or a polypropylene methylmethacrylate (PPM) sandwich mesh. PTFE is a flexible, soft material, while the PPM sandwich mesh resembles a hardened piece of plaster between two portions of woven mesh. Different surgeons prefer different approaches, but some of the benefits cited for the PTFE repair include greater stretch and the ability to create a water tight seal.⁷ The PPM sandwich repair on the other hand allows the ability to mold the prosthetic and provides a firmer stabilization (Fig. 80-9).⁹ Mortality rates from chest wall reconstruction in the setting of cancer resections have been reported at 4% in multiple series.^{7,9,10}

Flap coverage of the soft tissue defect will almost always require the assistance of a plastic surgeon, and they should be involved preoperatively in the planning of a chest wall resection and reconstruction. The decision-making process for which flap to use depends on the location of the defect, the size of the defect, the corresponding size of the flap, and its vascular source. Pectoralis major flaps are the most common in the upper chest/neck region. Its blood source can be from the thoracoacromial artery or from intercostal perforators from the internal thoracic arteries (Fig. 80-10). The latissimus dorsi flap is also commonly used for large, ipsilateral defects. Its blood source is from the thoracodorsal artery or from perforators from the posterior intercostal vessels. It has a large arc of rotation from the thoracodorsal pedicle and can cover a wide area of the chest wall (Fig. 80-11). Also commonly used are rectus abdominal muscle flaps in either a vertical (VRAM) or transverse (TRAM) orientation (Fig. 80-12). External obliques can be used on the lower anterior chest wall, and the trapezius can be used in the mid back.¹¹ Omental flaps are extremely useful and versatile. They can be used to cover large defects or to fill cavities, such as the pleural space in the setting of a bronchopleural fistula and empyema. The omentum can be taken off of the right or left gastroepiploic artery, but using the right arterial source allows a greater arc of rotation than from the left. The limitations of this flap are that it requires a laparotomy, although laparoscopic techniques have been described,¹² and that the size of the omentum can be variable, and difficult to assess preoperatively (Fig. 80-13).¹¹

CHEST WALL CONGENITAL ABNORMALITIES AND THORACIC OUTLET SYNDROME

Pectus Excavatum and Pectus Carinatum

Chest wall deformities occur in 1/1,000 live births. They are five times more common in men than women, and pectus excavatum is five times more common than pectus carinatum. Upto 6% of people with these deformities will also have a connective tissue disorder. Scoliosis is frequently seen in this population.¹³ Pectus excavatum appears as a sternal depression that can be off midline approximately 50% of the time. Pectus carinatum is the opposite, with a sternal protrusion, often described as a “pigeon chest” deformity. Less common deformities include sternal clefts, which are incomplete fusions of the sternum, and Poland syndrome, where there is an absence of a pectoralis muscle and underlying bony support in the chest wall.

Figure 80-9. Marlex methylmethacrylate sandwich technique for chest wall reconstruction. **A:** Upper anterior chest wall defect resulting from resection of ribs two to five and a portion of sternum. **B:** Marlex methylmethacrylate prosthesis being sutured in place. Heavy, nonabsorbable sutures either encircling the ribs or passed through the sternum are used to anchor the prosthesis in place. **Inset:** Detail of prosthesis showing sandwich of hardened methylmethacrylate between two sheets of Marlex.

Figure 80-10. Pectoralis major muscle rotation flap. **A:** Mobilization of the flap by detaching the clavicular, sternal, and chest wall origins as well as the insertion of the muscle on the greater tubercle of the humerus. The dominant blood supply, the thoracoacromial artery, which arises from the axillary artery medial to the proximal border of the pectoralis minor muscle, is shown on the left side where the pectoralis major muscle has been removed. **B:** Medial transposition of the muscle flap, preserving the thoracoacromial neurovascular bundle.

Figure 80-11. Latissimus dorsi muscle rotation flap for chest wall reconstruction. **A:** Posterior view showing detachment of the origins of the muscle. The dominant blood supply, the thoracodorsal artery, is preserved. **B:** Anterior view showing the extent to which the mobilized muscle reaches.

Figure 80-12. Rectus abdominis muscle rotation flap. Shown is the mobilization of the rectus abdominis muscle, which is based on the superior epigastric artery (the continuation of the internal thoracic artery), and rotation of the muscle and overlying skin to fill an anterior chest wall defect.

Figure 80-13. The omentum can be used to cover large defects. Shown is an open sternal wound after débridement with failed prior muscle flap (A), and wound 6 months after omental flap placement (B). (Reproduced with permission from Ghazi B, Carlson G, Losken A. Use of the greater omentum for reconstruction of infected sternotomy wounds: a prognostic indicator. *Ann Plast Surg* 2008;60(2):169–173.)

Pectus excavatum is the most common of these deformities, and the techniques for surgical correction have been evolving, including the Ravitch and Nuss procedures. Despite this, less than 15% of patients undergo surgery.¹⁴ Most patients present as children with notable deformities. People can be physiologically asymptomatic, but can also present with fatigue, limited stamina, and cardiopulmonary limitations. The workup includes pulmonary function testing, echocardiography, and CT scans. The use of CT scans has been debated in children as the radiation exposure poses a risk. Some advocate that CT scans are needed to show the three-dimensional aspect of defect and can better reflect the right heart compression. The pectus severity index (Haller index) can be calculated by dividing the inner thorax width by the depth measured from the posterior aspect of the sternum to the anterior aspect of the spine (Fig. 80-14). Normal values are 2 to 2.2, and repair is only recommended when the index is at least greater than 3.1.^{13,15} The age of the patient at which repair should be performed is also somewhat controversial, as some surgeons advocate waiting until after the age of 10, but many series have reported on a large number of patients treated at a much younger age with good outcomes.¹⁴ There is a growing experience with treating adults also, as some patients seek repair at a later age (Fig. 80-15).^{16,17}

Figure 80-14. Chest CT of pectus excavatum. CT image at xiphoid with A-B (transverse diameter) and C-D (anterior-posterior diameter) indicated for the calculation of the pectus severity index $A-B/C-D$ (A). CT image demonstrating angulation of the sternum to the right in the severe defect (B). (Reproduced with permission from Haller JA Jr, Scherer LR, Turner CS, et al. Evolving management of pectus excavatum based on a single institutional experience of 664 patients. *Ann Surg* 1989;209(5):578–582.)

Figure 80-15. Photograph of a 4.5-year-old girl with a symmetric pectus excavatum deformity. Note that the depression extends to the sternal notch. (Adapted with permission from Shamberger RC. Chest wall deformities. In: Shields TW, ed. *General Thoracic Surgery*. 4th ed. Baltimore, MD: Williams & Wilkins; 1994:529–557.)

The most commonly used open repair was first described by Dr. Ravitch and is based on removing sections of the deformed cartilage from around the sternum laterally at the ribs, while preserving the perichondrium. Many advocate using a stabilizing bar for a minimum of 6 months, usually placed in an intrathoracic position, to minimize the occurrence of flail chest and to allow the sternum to heal in an anterior position. An essential part of the procedure is a transverse sternal wedge resection through the anterior table to allow the inferior aspect of sternum to bend forward.^{13,17} Incisions may be in a vertical midline over the lower half of the sternum or in an inframammary position (Fig. 80-16). Recurrences occur in 5% to 10% of patients, with recurrence more common in patients with connective tissue disorders.

Since the 1990s, the Nuss procedure, which utilizes a minimally invasive approach, has been described and performed. The Nuss procedure utilizes one or two stabilization bars, secured to the ribs laterally in multiple points of fixation. It routinely employs thoracoscopy, either unilateral or bilateral. Skin incisions are limited to small lateral locations at the site of the bar insertion and thoracoscopic port-sites. In both the Ravitch and Nuss procedures, the stabilization bars stay in for at least 6 months.¹⁸ As the Nuss procedure has grown in popularity, many modifications have been made, including precise shaping of the bars and increased bar stabilization with wire fixation around the ribs to minimize bar displacement.¹⁹

Pectus carinatum does not have the same cardiac compression concerns as pectus excavatum, but the chest is held in an enlarged position, limiting normal respiration mechanics. Patients can have increased residual lung volumes and their respiratory physiology can mimic emphysema physiology. This can result in breathing difficulties and limited stamina.¹⁷ The Ravitch procedure is most commonly performed to remove the deformed cartilage. Special attention is placed on the transverse sternal osteotomy, to depress the sternum and align it with the anterior ribs (Fig. 80-17).¹³

A

B

Figure 80-16. A chevron incision is made with flaps elevated. The perichondrium on the deformed cartilage is removed (A). A transverse wedge osteotomy is made across the anterior table of the sternum. The lower sternum is elevated to the desired level (B). A metal strut is placed posterior to the sternum and attached to the ribs with fine wire (C).

Sternal Clefts

Sternal clefts are much rarer than either pectus deformity. They result from the failure of the sternum to fuse in the midline. They can vary from minor defects with the upper half of the sternum separated, to complete dissociation and thoracic ectopia cordis (the heart being outside the chest wall). Upper sternal defects have a U- or V-shaped appearance and usually extend to the fourth intercostal space (Fig. 80-18). Repair of these defects can be easily performed by incision, complete sternotomy, oblique chondrotomies of the sternal halves, and closure. Complete sternal clefts are associated with diastasis recti and an opening between the peritoneal and pericardial cavities. Inferior clefts are associated with the pentalogy of Cantrell, a constellation of defects which include supraumbilical abdominal wall defect, lower sternal cleft, defect in the anterior diaphragm, defect in the associated pericardium, and congenital cardiac defects, often tetralogy of Fallot. With the increased use of prenatal ultrasound, most cases are diagnosed early and are being appropriately referred to specialists prior to birth.²⁰

Figure 80-17. Photograph of (A) symmetric chondrogladiolar pectus carinatum in a 19-year-old man. Postoperative photograph (B) shows correction of the protruding sternum and costal cartilages. (Adapted with permission from Shamberger RC. Chest wall deformities. In: Shields TW, ed. *General Thoracic Surgery*. 4th ed. Baltimore, MD: Williams & Wilkins; 1994:529–557.)

Figure 80-18. Cleft sternum at rest (A) and during forced expiration (B). Superior clefts of the sternum are variously V- or U-shaped. The appearance of the child as he cries explains the term ectopia cordis, although the heart is actually not misplaced. In the newborn, defects of this kind can be corrected by direct apposition of the sternal halves. In this child, closure of the defect was made possible by sliding chondrotomies on either side. (Reproduced with permission from Sabiston DC Jr. The surgical management of congenital bifid sternum with a partial ectopia cordis. *J Thorac Surg* 1958;35:118.)

Poland Syndrome

Poland syndrome is the clinical absence of a pectoralis muscle and underlying bony support in the chest wall, and it occurs in 1/30,000 live births. It is usually a right-sided, unilateral defect. Patients commonly have associated limb abnormalities, and may also present with renal and spinal lesions (Fig. 80-19). Clinical symptoms may be absent, though lung herniation can occur, requiring a more urgent repair. The surgical approach is usually multidisciplinary and ideally is deferred until after the patient has stopped growing. Repairs typically utilize mesh placement over the defect, and/or muscle flap placement.²¹

Thoracic Outlet Syndrome

2 The thoracic outlet in thoracic outlet syndrome (TOS) refers to the area described at the beginning of this chapter as the thoracic inlet, the correct anatomic term for the region of the first rib and the middle and anterior scalene muscles. Through these structures, the brachial plexus, subclavian artery, and subclavian vein travel to the upper limbs (Fig. 80-20). Because of the close proximity in this area, these conduits may be subjected to abnormal compression by inflammation around the muscles or abnormal bony structures such as cervical ribs, causing pain, thrombosis, and other symptoms that are described as TOS. TOS can be divided into arterial, venous, or neurogenic diseases, or a combination, depending on the symptoms and clinical findings. Vascular TOS is easier to document with vascular imaging. Neurogenic TOS is more difficult to diagnose. Unfortunately for neurogenic TOS, there is no gold standard diagnostic test to confirm the syndrome. As a result, there has been significant controversy over the diagnosis and the indications for surgical treatment, especially in light of the potential for significant postoperative complications.^{22,23}

Vascular TOS can be divided into venous disease and arterial disease. Venous disease results in thrombosis of the subclavian vein and is also called Paget-Schroetter syndrome. This syndrome usually presents in men who use their upper bodies and dominant arm for work. Symptoms may present as pain, swelling, and cyanotic discoloration.²² Contrast venography is the best test to make the diagnosis, and the radiologist should be instructed to perform positional maneuvers with the patient's arm to replicate narrowing that occurs with arm movement.²³ Arterial TOS accounts for about 5% of all cases of TOS²⁴ and also may result from repetitive and strenuous use. Patients will present with arm fatigue and may even have evidence of ischemia in their distal digits. Patient evaluation includes pulse examination with the arm relaxed and elevated, bruit examination for poststenotic dilatation, and blood pressure readings in both arms. Duplex scanning and angiography will often confirm the diagnosis. Decompression of the scalene muscles and any abnormal bony structures will alleviate these symptoms.²²

Neurogenic TOS presents with limb pain, numbness, or weakness. Symptoms may be bilateral, but are usually worse in the dominant arm. The distribution may not follow a peripheral nerve pattern, thus making the diagnosis confusing, but also ruling out more distal compression syndromes such as carpal tunnel in the wrist or cubital compression at the elbow. The physical examination should be focused on duplicating the patient's symptoms. The Adson maneuver may detect artery compression and is performed by palpating the affected radial pulse, and having the patient take a deep inspiration while turning their head away from the affected arm (Fig. 80-21). The test is positive if the pulse disappears, but a positive result can also be seen in asymptomatic people without TOS. Another test requires the patient to elevate their arms in a "surrender" position and open and close their hands repeatedly. Most people with neurogenic TOS will be fatigued within a minute and be unable to continue (Fig. 80-22). Plain radiographs may show bony abnormalities, but no other imaging will help diagnose neurogenic TOS. Physical rehabilitation is the first step to treat patients with neurogenic TOS, and over a third of patients may get a significant improvement in their symptoms. If there is no significant improvement in symptoms, then surgical intervention is suggested.²³

Figure 80-19. A: Muscular 15-year-old boy with loss of the left axillary fold, orthotopic sternum, and normal cartilages. He compensates adequately for loss of the pectoralis major and minor muscles. Surgery is not indicated in males with these findings. B: An 8-year-old boy with Poland syndrome. The pectoralis major and minor muscles and the serratus to the level of the fifth rib are absent. The boy has sternal obliquity, and the third to fifth ribs are short, ending in points. The corresponding cartilages are absent. The endothoracic fascia lies beneath a thin layer of subcutaneous tissue. Note the hypoplastic nipple and ectromelia of the ipsilateral hand. C: A 14-year-old girl with Poland syndrome. Note the high position of the right nipple, amastia, sternal rotation, and depressed right anterior chest. The second to fourth ribs and cartilages were missing, reconstructed with rib grafts. Breast

The surgical approach for TOS was traditionally a transaxillary first rib resection (Fig. 80-23). In recent years, a supraclavicular approach has become increasingly popular as it gives better exposure to the scalene muscles and any cervical ribs. In either approach, the first rib is exposed and the anterior and middle scalene muscles are removed from their attachments to the rib. Once this is performed, the first rib is removed (Fig. 80-24). Special attention must be paid to the phrenic nerve lying along the anterior scalene and the axillary branches off of the brachial plexus. Small drains may be placed in the apex of the thorax if the pleural space is entered.^{23,25} The supraclavicular approach also gives access to perform a cervical sympathectomy if indicated for symptoms consistent with sympathetic overactivity. In patients with arterial aneurysms, reconstruction with synthetic grafts or autologous conduits such as an external iliac artery can be performed. For patients with venous TOS, care should be taken to perform a circumferential venolysis and to remove the medial aspect of the first rib.²⁵

Postoperative complications include pneumothorax, lymphatic leaks, especially on the left side where the thoracic duct enters the operative field, phrenic nerve palsy, and traction injury to the brachial plexus.²⁴ Patients should have good pain control and may need muscle relaxants to minimize muscle spasm. There should be limited restrictions to the operated extremity to maximize movement and minimize the risk of developing a frozen shoulder. Rehabilitation should be restarted as soon as possible after surgery.^{23,25} Upto 12.5% of patients may not get any symptom relief after the surgery, and long-term physical rehabilitation is recommended.²⁴ Patients with combined symptoms of venous and neurogenic TOS have worse outcomes when compared to patients with only venous disease. A higher percentage of patients had persistent pain in the neurogenic group as might be expected.²⁶ The treatment of this disease process requires a significant investment into the preoperative and postoperative care of these patients and should only be done in centers with a high volume and expertise in this syndrome.

Figure 80-22. Surrender position with opening and closing of hand. Early fatigue is seen in neurogenic TOS.

NONNEOPLASTIC LUNG DISEASE

Lung Abscess and Bronchiectasis

3 Complications from pulmonary infections that require surgery are not common relative to the frequency of pneumonias in both the inpatient and outpatient community. However, in some patients, treatment of lung abscesses and bronchiectasis may include surgical intervention. Lung abscesses can result from aspiration or occur after necrotizing pneumonia. Patients may present with chest pain and fever. Routine use of antibiotics for pneumonias has dramatically reduced the rate of lung abscess sequelae. In over 80% of cases, a pathogen can be found, and in immunocompromised patients, there are usually multiple organisms involved including *Pseudomonas aeruginosa* and *Haemophilus* species. The primary treatment for lung abscesses is medical therapy with antibiotics. If a patient is clinically not improving with medical therapy alone, a guided drainage tube may be placed. A complication of this approach is the risk of a chronic air leak from a percutaneous tube placed into the lung parenchyma. Surgery may be indicated in the setting of large abscesses causing hemoptysis or other symptoms ([Algorithm 80-1](#)). Surgical resection may also be of clinical benefit in some patients by removing lung tissue damaged by necrotizing pneumonia.²⁷

Bronchiectasis is the abnormal dilation of bronchi/bronchioles as the result of multiple episodes of

infection and inflammation. Factors contributing to the development of this disease may be genetic, anatomic, or even systemic. Genetic causes include cystic fibrosis, which results in diminished mucus clearance and diffuse bronchiectasis in both lungs.²⁸ Primary ciliary dyskinesia is an autosomal recessive syndrome resulting in abnormal cilia that cannot clear secretions leading to multiple infections. Individuals with alpha-1-antitrypsin deficiency can also develop bronchiectasis. Anatomic causes include postsurgical changes or acquired diseases such as chronic obstructive pulmonary disease (COPD) that lead to an increased risk of infection, again by the inability to clear secretions. Autoimmune diseases such as rheumatoid arthritis and inflammatory bowel disease have been associated with increased rates of bronchiectasis.^{28,29} Infectious causes include allergic bronchopulmonary aspergillosis and nontuberculous mycobacterium infections. Reflux disease is also being studied as a potential contributor. Most often the etiology of the disease is idiopathic.²⁸

Figure 80-23. Position of the patient (A) and skin incision (B) for transaxillary approach. (Reproduced with permission from Scott-Conner CE, Dawson DL, Shirazi MK, et al. *Operative Anatomy*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2008.)

There are estimated to be 110,000 patients in the United States being treated for noncystic fibrosis bronchiectasis each year. The diagnosis is increasingly being made as a result of an increasing number of chest CT scans being performed for other, nonrelated reasons. Patients can present with respiratory symptoms like dyspnea, hemoptysis, or pleuritic pain, or alternatively may present only with systemic changes such as fatigue and weight loss.²⁸ Almost all patients will have a chronic cough with or without sputum production.²⁹ Pulmonary function tests may demonstrate moderate to severe airflow

obstruction.²⁸ A chest CT scan is the optimal test to diagnose bronchiectasis (Fig. 80-25), and once the diagnosis is made, the search for an etiology should begin, including obtaining sputum cultures and blood tests for autoimmune markers such as rheumatoid factor.²⁹

The treatment of the disease includes antibiotic therapy to control infection, the treatment of underlying diseases if they exist, reducing inflammation, improving secretion clearance, and surgery to remove focally damaged areas or transplantation if needed for more diffuse, severe disease. Antibiotic therapy includes inhaled tobramycin and gentamicin.²⁹ Macrolide antibiotics have been increasingly studied for their nonantibiotic effects. Erythromycin and clarithromycin have anti-inflammatory benefits. They disrupt the biofilm produced in *Pseudomonas* infections resulting in decreased sputum volume and improved symptoms.³⁰ Secretion removal is also essential to improving symptoms. Besides the standard treatments of percussive therapy and postural drainage, the use of nebulized acetylcysteine²⁹ or hypertonic saline³⁰ has been shown to improve mucus clearance.

Figure 80-24. Division of the scalene muscles and the first rib. **A:** Mobilization of the scalene muscles off of the first rib. **B:** Exposure of the subclavian vessels. **C:** Mobilization of the first rib, protecting the vessels. (Reproduced with permission from Scott-Conner CE, Dawson DL, Shirazi MK, et al. *Operative Anatomy*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2008.)

Surgical intervention may occur at many stages of the disease process. Bronchoscopy can be useful to clear secretions or to manage hemoptysis. If the bronchiectasis is localized to a single lobe, resection can eliminate the disease and the source of chronic infection. If a patient has a genetic disease such as cystic fibrosis, a double lung transplant may be the best treatment if the patient's symptoms are severe enough.²⁹ Pulmonary tuberculosis can have similar indications for surgical intervention when it results in bronchiectasis or hemoptysis.³¹ The rise of more multidrug-resistant tuberculosis strains has led to the increasing need for surgical intervention.³²

Hemoptysis

4 Hemoptysis is often used to describe any blood streaking associated with cough. True hemoptysis may only be a few drops of blood, and it requires investigation. Massive hemoptysis is acutely life threatening, not from blood or volume loss, but rather from suffocation secondary to blood in the airway. The immediate goals when this is encountered are airway control, improved oxygenation, and resuscitation if needed. Intubation may or may not be necessary, depending on the volume of blood in the airway and the patient’s ability to cough.³³ If the bleeding is able to be lateralized, the patient should be placed in a lateral decubitus position with the bleeding site in the dependent position. The causes of hemoptysis include cancer, infections/bronchiectasis, vascular injuries, vasculitides, and coagulopathies.³⁴

In patients with hemoptysis, any coagulopathy should be corrected. Early bronchoscopy is essential and the goals are to lateralize the site of bleeding and identify the site and cause of the bleeding. Flexible bronchoscopy may be done, but rigid bronchoscopy is the best approach to maintain airway control, in particular in the setting of large volume hemoptysis. Initial treatment may include topical therapy such as cold saline lavage, bronchial tamponade, and intubation of the contralateral good lung. Double-lumen endotracheal tubes may also be useful to isolate and protect the uninvolved lung from blood from the contralateral side obstructing its lumen.³³ If a patient is stable, a chest CT scan is useful to identify tumors or other potential sources of bleeding.³⁴

Algorithm 80-1. Algorithm for management of lung abscess. (Adapted from Shields TW, ed. *General Thoracic Surgery*, 6th ed. 2005.)

Once a patient is stabilized and appropriate diagnostic tests performed, the treatment of continued bleeding includes the use of interventional radiology and bronchial artery embolization (BAE).³⁵ First introduced in 1973, BAE is the best nonsurgical treatment of massive hemoptysis, with a success rate of upto 98% within 24 hours.³⁴ Surgery is reserved to treat the underlying condition once the patient has been stabilized and bleeding controlled by other methods. Emergent surgery to treat bleeding may have a mortality rate as high as 38%,³⁵ and increase to 59% in the setting of malignancy.³⁴ Depending on the patient’s baseline lung function, a lobectomy, let alone a pneumonectomy, may not be tolerated. A risk assessment of the benefits of surgery must be performed. In the setting of a vascular etiology of the hemoptysis such as a ruptured aortic aneurysm, surgical repair is essential and should not be delayed once the patient is hemodynamically stable and the airway is controlled.³⁴ A detailed algorithm in the assessment and treatment of hemoptysis is shown in [Algorithm 80-2](#).

COPD and Lung Volume Reduction

COPD includes a broad group of diseases that result in airflow obstruction and hyperinflation. Medical therapy involves smoking cessation, bronchodilator treatment, steroids, home oxygen, and antibiotics as needed. Despite improvements in the medical management of this condition, patients continue to suffer severe limitations due to their breathing and exercise capacity. As a result, surgical interventions have continued to play a role in trying to ameliorate symptoms and improving survival in these patients.^{36,37}

There is a more than 50-year history in the literature recording a variety of surgical approaches to help treat COPD. Interest was diminished, however, because of the high mortality associated with surgical intervention in this patient population. In the 1990s, a renewed interest in lung volume reduction surgery (LVRS) was observed following reports that this procedure was associated with a low published mortality rate and a significant improvement in FEV₁ seen on pulmonary function testing. There was a national increase in interest in the procedure, as many centers began offering it. Despite continued publication of low mortality rates, evaluation of Medicare data in 1996 showed a mortality of 23% in surgically treated patients at 12 months, and Medicare reimbursement for the procedure stopped. This led to the development of the National Emphysema Treatment Trial (NETT), a prospective randomized trial to evaluate the outcomes of LVRS compared to optimal medical treatment.³⁶

Algorithm 80-2

Algorithm 80-2. Hemoptysis management. (Adapted from Jean-Baptiste E. *Crit Care Med* 2000;28(5):1642–1647.)

The goal of the NETT study was to evaluate short- and long-term survival, lung function, exercise capacity, and quality of life. Centers used both median sternotomy and bilateral video-assisted thoracoscopic surgery (VATS) approaches to perform the operative procedure. Interim analysis identified a high-risk subgroup with a higher mortality. These patients had low FEV₁ (less than 20% predicted) and either a homogenous pattern of emphysema in both upper and lower lungs or a low carbon monoxide diffusing capacity (DLCO) (less than 20% predicted). The mortality at 30 days was 16% and the risk was felt to be prohibitive. As the study continued, two preoperative factors appeared to be associated with decreased mortality; dominant upper-lobe emphysema and having a higher preoperative exercise capacity. Using these factors, patients were divided into four subgroups. Patients with upper-lobe disease and a low exercise capacity, defined as achieving less than the 40th percentile on exercise testing, 25 watts for women and 40 watts for men, showed a survival advantage and improved exercise capacity after surgery. Patients with upper-lobe disease and high exercise capacity, achieving more than the 40th percentile cutoff, showed no survival advantage, but did have improved long-term exercise capacity. Patients with nonupper-lobe disease and low exercise capacity had no survival or exercise improvements, but did note an improved quality of life at 24 months. The remaining patients with nonupper-lobe disease and high exercise capacity had a higher risk of death and no significant improvement in exercise capacity or quality of life. The 30-day mortality in the nonhigh-risk subgroup was 5.5%. Long-term follow-up showed the same results in all subgroups except in the nonupper-lobe disease and low exercise capacity group. The quality of life improvement had disappeared by 3 years (Algorithm 80-3).³⁶ This subgroup analysis has allowed surgeons to better counsel patients as to the benefits of LVRS, based upon which group they fall in.

When the different surgical approaches were evaluated, there was no difference in mortality or benefit from sternotomy versus VATS approaches. Sternotomy patients had a longer hospital stay and higher costs noted at 6 months. The cost effectiveness of LVRS was also evaluated. The mean cost for LVRS was much higher at 1 year than for the medical therapy group, \$71,515 versus \$23,371, respectively.³⁸ In the subgroup with upper-lobe disease and low exercise capacity, at 2 years of follow-up, there was a cost of \$98,000 per quality-adjusted life-year (QALY). This was predicted to fall to \$21,000 at 10 years. In comparison, coronary artery bypass graft surgery has a cost of \$64,000 per QALY.^{38,39}

A new technique aimed to provide the same benefit of LVRS but without the surgical risk is the placement of one-way endobronchial valves. These are designed to allow air to escape the hyperinflated apical regions and not allow air to reenter. Endobronchial stents have been designed to cross bronchioles into hyperinflated regions of the lung and allow decompression. Other approaches being

tested include the bronchoscopic introduction of biologic substances such as trypsin or thrombin into hyperinflated regions of the lung with the goal of causing local scarring and reduce the hyperinflation.³⁸ Other surgical procedures in the treatment of COPD include bullectomy in selected patients and lung transplants in patients with end-stage disease.³⁷

Algorithm 80-3. LVRS candidate workup. (Adapted from Martinez FJ, Chang A. *Semin Respir Crit Care Med* 2005;26(2):167–191.)

Tracheobronchial Foreign Body Aspiration

Tracheobronchial foreign body (TFB) aspiration occurs most often in children, but upto 20% of cases have been reported in adults. Risk factors in adults include older age, as elderly patients have a higher incidence of neurologic disease and an impaired cough reflex. Symptoms usually involve an episode of choking, followed by a protracted cough. Fever, dyspnea, and wheezing can also be present.⁴⁰ Chest x-ray may aid in the diagnosis if the aspirated TFB is radio-opaque or if there is associated air trapping, atelectasis, or pneumonia, however, the TFB is visible less than a quarter of the time as most foods are not radio-opaque.⁴¹ Chest CT scans are a more sensitive imaging modality, but not necessarily more specific. Bronchoscopy should be performed if TFB aspiration is suspected. Removal of the TFB can usually be accomplished by flexible bronchoscopy but may require rigid bronchoscopy in difficult cases.^{40,41}

Pneumothorax

Pneumothoraces are classified as spontaneous, primary or secondary, traumatic, or iatrogenic. Primary spontaneous pneumothoraces occur in patients with no known lung disease, whereas secondary spontaneous ones occur in patients with underlying lung pathology thought to predispose those patients to a pneumothorax. Iatrogenic pneumothoraces may occur in either the postsurgical or postprocedural setting, typically following central line placement or thoracentesis.⁴² Traumatic pneumothoraces are covered elsewhere in this text.

Primary spontaneous pneumothoraces occur more frequently in men than women, with an incidence of 7 to 18 cases per 100,000 people for men, compared to an incidence rate of 1 to 6 cases per 100,000 people in women. Most cases occur in males younger than 30 years of age, and they rarely occur in people over the age of 40. Even though many patients with primary pneumothoraces do not have apparent lung disease, almost all are found to have subpleural bullae, the pathophysiology of which is unknown.⁴² Most bullae are apical in location.⁴³ Patient symptoms can range from minimal to severe, and usually include pleuritic pain, dyspnea, or both. Tachycardia may also be present, and if a person is tachycardic and hypotensive, a tension pneumothorax must be high on the differential and appropriate needle decompression considered. A tension pneumothorax occurs when air entering the pleural cavity

cannot escape and the air compresses the vena cava and even the heart, resulting in hemodynamic instability (Fig. 80-26). Urgent needle decompression followed by chest tube placement is the preferred treatment. Most spontaneous pneumothoraces occur while patients are at rest.^{42,44}

5 Observation is often the treatment of a stable, small pneumothorax, defined as being less than 3 cm from the apex. For a larger pneumothorax, chest tube placement is the standard treatment, though some advocate a trial of aspiration. Most patients will have a complete resolution of their pneumothorax and not need further treatment. In the group of patients who have a persistent air leak from the initial pneumothorax, or the 30% who have a recurrent pneumothorax, usually within 2 years, further treatment is warranted. This involves some form of pleurodesis, chemical or mechanical, either via a chest tube (talc infusion), or during a thoroscopic evaluation where apparent blebs can also be resected (Algorithm 80-4).^{43,44}

Secondary spontaneous pneumothoraces can occur due to a variety of lung diseases, but COPD is the most common.⁴⁵ While primary pneumothoraces can be mild clinical events, secondary ones are much more concerning because of the baseline lung disease and poor pulmonary reserve. Observation has no role in this patient population who should undergo definitive treatment to prevent a recurrence during the first event. Here a thoroscopic approach may be more effective in establishing an adequate pleurodesis and allow the evaluation for sources of air leaks.⁴⁴ Iatrogenic pneumothoraces can result from transthoracic needle lung biopsies, central line placement, thoracentesis, transbronchial lung biopsies, pleural biopsies, and positive pressure ventilation. Patients with underlying lung disease are at a higher risk of developing a pneumothorax after these procedures. Treatment should follow the same paradigm as for spontaneous pneumothoraces. Patients with a small, asymptomatic, stable pneumothorax and no underlying lung disease may be safely observed, while all others should undergo placement of a chest tube.⁴⁴ Some studies have suggested immediate aspiration of air after a CT-guided lung biopsy resulting in a pneumothorax, with an 85% success rate in avoiding the need for chest tube placement.⁴³

Figure 80-26. A: A 40% left-sided spontaneous pneumothorax (arrow). B: Progression of simple pneumothorax to a tension pneumothorax, showing the characteristic radiographic findings – virtual collapse of the entire involved lung, shift of the mediastinum to the contralateral side, and compression of the contralateral lung. Subcutaneous air dissecting along the left chest wall is also evident.

Congenital Lung Disease

Congenital malformations of the lung develop during fetal lung growth. They may be identified during an in-utero evaluation, present as respiratory distress in the newborn, or be completely asymptomatic and found in patients as adults. They can frequently occur with other congenital malformations and may be life-threatening. Lung development begins during week 3 from the foregut. It progresses through birth to approximately 2 years of age when alveolar development is complete. The five stages of lung development have been divided into the embryonic, pseudoglandular, acinar, saccular, and alveolar stages (Table 80-2). Malformations may occur at each step and lead to different pathologic conditions.⁴⁶ Four separate conditions will be discussed here; pulmonary sequestration, lobar emphysema, congenital

cystic adenomatoid malformation (CCAM), and bronchogenic cysts.⁴⁷

Algorithm 80-4. Algorithm to treat pneumothorax. (Adapted from Baumann MH, Noppen M. *Respirology* 2004;9(2):157–164.)

Table 80-2 Phases of Lung Development Classification

Phase	Gestation Period	Major Developments
Embryonic	26 days to 6 wks	5 lobar bronchi
Pseudoglandular	6–16 wks	Cartilage rings, cilia form
Acinar/canalicular	16–28 wks	Type I and II pneumocytes
Saccular	28–34 wks	Distal airspace development
Alveolar	34 wks to 2 years	Alveoli proliferate from 20 to 600 million

Pulmonary Sequestrations

Pulmonary sequestrations are defined as pieces of parenchymal lung separated from the respiratory tree, with the sequestration receiving its blood supply from an anomalous artery arising from the aorta, rather than having the blood supply arising from the pulmonary artery. Sequestrations have been further subdivided into extralobar and intralobar lesions, with very distinct anatomic alterations and clinical presentations. Extralobar sequestrations reside outside of the true pleural space. Venous drainage is usually into the azygos or hemiazygos veins. They are most often on the left side between the left lower lobe and diaphragm (Fig. 80-27). Upto 80% of extralobar sequestrations occur in males. Most patients present with dyspnea in the first 6 months of life. They may be diagnosed by fetal ultrasound or after birth by chest x-ray. Other congenital abnormalities are found in upto two-thirds of patients, with congenital diaphragmatic hernias present in a quarter of patients.⁴⁶ Intralobar lesions reside within the normal lung and within the normal pleura. They are almost always in the lower lobes and occur in the left side just over 50% of the time. Venous drainage is usually through the pulmonary vein. It is suggested that intralobar sequestration may be an acquired disease, caused by repeated episodes of inflammation that lead to bronchiole narrowing and scarring. Ultimately the “lobe” becomes isolated and may develop new feeding blood vessels from collateral arteries in the inferior pulmonary ligament. A complete assessment of a sequestered lesion must be performed prior to resection, and should include assessment of any potential airway or gut connection, determining the vascular supply of the sequestration, and determining if there are any other congenital malformations.⁴⁶

Figure 80-27. Abnormal radiograph of the chest of a newborn with respiratory distress (A). Ultrasound identified the anomalous vessel coursing through the diaphragm and entering the sequestration (B). This computed tomographic scan clearly demonstrates the anomalous artery arising from the thoracic aorta and entering the sequestered lung (C). (Reproduced with permission from Shields TW, ed. *General Thoracic Surgery*. 6th ed. 2005.)

Figure 80-28. Radiograph of a newborn with lobar emphysema involving the right middle lobe. Note the compressed right lower lobe and mediastinal shift. (Reproduced with permission from Shields TW, ed. *General Thoracic Surgery*. 6th ed. 2005.)

Congenital Lobar Emphysema

Lobar emphysema is the cause of half of the episodes of newborn respiratory distress that are due to structural anomalies. Two-thirds of the cases occur in males. Distension of the distal lung occurs from obstruction of the airway, either from an intrinsic cause, such as meconium or torsion, or an extrinsic cause, such as obstructing lymph nodes. In up to half of the cases, no cause can be found. Almost all cases occur in the upper lobes, with almost equal distribution between sides. Half of the lesions will present in newborns, and the remaining 50% will reveal themselves by 6 months. Chest x-rays are diagnostic (Fig. 80-28).⁴⁶ Surgical resection may not be immediately necessary, and may be delayed until the child has grown, or until they develop a failure to thrive. Even after surgical resection, patients

may have bronchomalacia and a tendency toward bronchospasm.⁴⁸

Congenital Cystic Adenomatoid Malformation

CCAM lesions are the second most common cause (25%) of newborn respiratory distress, secondary to structural problems. Children will present either at birth or in early childhood with recurrent respiratory infections. The anomalies are due to an overgrowth of bronchioles, likely during the acinar phase of fetal lung development. Lesions can occur on either side and are usually isolated to one lower lobe. The classification system by Stocker (Table 80-3) organizes these lesions based on pathologic appearance and clinical outcome. Prenatal MRI best serves to evaluate these lesions, while postnatal chest x-ray and/or chest CT scan can be used to differentiate CCAMs from other lesions.⁴⁶ Even though lesions may be small and asymptomatic, these lesions possess the potential for malignant transformation and should be resected (Fig. 80-29).⁴⁸

Table 80-3 The Stocker Classification of CCAM

■ Type I
75% of lesions
Few large cysts
Parenchymal compression
■ Type II
Numerous, <1 cm cysts
Associated with other congenital anomalies
Worse prognosis
■ Type III
Rarest type
Cysts are solid and smaller (few mm in diameter)

Figure 80-29. Specimen removed from an infant with a cystic adenomatoid malformation. Microscopically, there was marked proliferation of terminal bronchioles, and cartilage was lacking. (Reproduced with permission from Shields TW, ed. *General Thoracic Surgery*. 6th ed. 2005.)

Bronchogenic Cysts

Bronchogenic cysts are formed from primitive foregut tissue present in the airway. They can present as single or multiple cysts in a wide variety of locations in the thorax. They usually present in young children who develop symptoms such as stridor due to airway obstruction or compression caused by the cysts.⁴⁷ Alternatively, cysts located within the lung parenchyma can become infected and present as an abscess. Therapeutic aspiration may be temporizing, but ultimately surgery is needed.⁴⁹ Resection may have a mortality of upto 14%, but untreated lesions have a 100% mortality.⁴⁷ Most cases of congenital lung disease will present in the first 6 months of life. The main symptom is usually respiratory distress,

but once children reach 1 year in age, chronic infections become the most common symptom. Diagnostic tests begin with chest x-rays, but can include ultrasound, MRI, CT scans, angiography, and bronchoscopy, depending on the lesion and location.⁵⁰ Decision-making regarding the timing of surgical resection should incorporate the patient’s acuity due to symptoms and their overall ability to tolerate surgery based on size.

Pleural Disease

Pleural diseases include benign complications from systemic disease, postoperative infections, local infections, and cancers from primary and metastatic sites. Diseases involving the pleura can lead to limitations to respiration and symptoms of dyspnea. Surgical intervention may be indicated, and it is imperative for the surgeon to be able to recognize which disease processes require a surgical procedure. Pneumothoraces are discussed earlier in this chapter, and here we will cover pleural effusions, including empyemas, and malignant pleural mesotheliomas.

DIAGNOSIS

Table 80-4 Differential Diagnosis of Pleural Effusions

Transudative pleural effusions	Collagen vascular diseases
Congestive heart failure	Rheumatoid pleuritis
Pericardial disease	Systemic lupus erythematosus
Cirrhosis	Drug-induced lupus erythematosus
Nephrotic syndrome	Immunoblastic lymphadenopathy
Peritoneal dialysis	Sjögren syndrome
Superior vena cava obstruction	Wegener granulomatosis
Myxedema	Churg–Strauss syndrome
Pulmonary emboli	Postcardiac injury syndrome
Sarcoidosis	Asbestos exposure
Urinothorax	Sarcoidosis
Exudative Pleural Effusions	Uremia
Neoplastic diseases	Meigs syndrome
Metastatic disease	Yellow nail syndrome
Mesothelioma	Drug-induced pleural disease
Infectious diseases	Nitrofurantoin
Bacterial infections	Dantrolene
Tuberculosis	Methysergide
Fungal infections	Bromocriptine
Viral infections	Procarbazine
Parasitic infections	Amiodarone
Pulmonary embolization	Trapped lung
Gastrointestinal disease	Radiotherapy
Esophageal perforation	Electric burns
Pancreatic disease	Urinary tract obstruction
Intra-abdominal abscess	Iatrogenic injury
Diaphragmatic hernia	Ovarian hyperstimulation syndrome
Postabdominal surgery	Chylothorax
Endoscopic variceal sclerotherapy	Hemothorax

PLEURAL EFFUSIONS

Pleural effusions are a common condition that elicits a surgical consult for potential drainage and even thoracoscopic intervention to assist in the diagnosis and treatment of the condition. The essential first step in the evaluation of a new effusion is to determine if it is a transudative or exudative process. A transudative fluid collection is the result of a poorly balanced hydrostatic and/or osmotic pressure across the pleural membrane resulting in increased serum leak across the pleural barrier. Exudative processes result from inflammation or neoplastic processes that cause increased capillary leak at the pleural membrane. Because of the leaky membrane, larger proteins can enter the pleural fluid resulting in higher protein and lactate dehydrogenase (LDH) levels in the exudative fluid compared to the

transudative fluid (Table 80-4).⁵¹ One of the tests used most often to make the diagnosis is Light criteria, where the serum and pleural fluid protein and LDH levels are measured (Table 80-5). If one or more of the criteria are met, then the fluid is considered exudative.⁵² Other tests have been evaluated, including measuring cholesterol ratios and the albumin gradient, but Light criteria is still the best overall test.⁵¹

6 Transudative effusions are most often caused by congestive heart failure. Even if a patient does not have other symptoms of heart failure, in the setting of a transudative effusion, a complete cardiac workup should be considered. Other causes include cirrhosis which may or may not be associated with ascites. Isolated right- and left-sided effusions due to liver disease have been described. Effusions can be seen in more than 20% of patients with nephrotic syndrome, and so all patients with new effusions should be evaluated for the presence of proteinuria. Rarer causes include retroperitoneal urine leaks or cerebrospinal fluid leaks.⁵² Surgical interventions, such as chest tube placement, should be avoided in transudative disease settings, as patients will continue to drain fluid from their chest until the primary cause is treated. Aspiration of fluid may help temporarily while systemic treatment is instituted, but should only be done as part of a larger treatment plan.

Table 80-5 Criteria for Exudative Effusions Based on Ratio of Pleural Fluid Protein and LDH Concentrations to Serum Concentration

Protein/serum protein >0.5
LDH/serum LDH >0.6
Pleural LDH 1.67 times normal serum LDH

LDH, lactate dehydrogenase.

Exudative effusions have a number of etiologies, but malignancy is the number one cause.⁵² Approximately a quarter of pleural effusions in a community hospital setting have been attributed to cancer. The malignancies that cause the effusions are, in order of decreasing frequency: lung cancer, breast cancer, and hematologic cancers such as lymphoma. Other malignancies can also cause effusions, such as ovarian cancer.⁵³ The next most common causes of exudative effusions are infections, and include pneumonias causing parapneumonic effusions, tuberculosis (TB), and fungal infections. Although rarer in the United States, TB is still a common etiology worldwide. If someone is suspected of having pleural TB, the pleural fluid should be evaluated for adenosine deaminase (ADA) and gamma-interferon levels, which if low will rule out the diagnosis of TB. If other infections are suspected, the pleural fluid should be cultured. Pancreatitis may also cause an exudate, and elevated serum amylase levels will support the diagnosis. Autoimmune processes, such as rheumatoid disease and lupus, can also cause effusions. A chylothorax may present after problems with thoracic duct lymphatic drainage leading to an accumulation of lymphatic fluid, “chyle”, in one or both thoraces. The thoracic duct collects lymph from the cisterna chyli, the plexus of lymphatics in the upper abdomen, and travels anterior to the spine and just posterolateral to the aorta. It follows behind the aorta and enters the left neck where it empties into the confluence of the left internal jugular and subclavian veins (Fig. 80-30). Chylous leaks are due primarily to thoracic duct injury from trauma or surgery or lymphomas resulting in obstructed lymphatics. Pleural triglyceride and cholesterol levels will be elevated and the fluid will have a milky color. Treatment for persistent chylothoraces include thoracic duct ligation by surgery or by embolization of the site of leak in the interventional suite.⁵²

The management of malignant pleural effusions includes a variety of options, but critical to the decision-making process is the knowledge of the median life expectancy in that patient due to the underlying malignancy. Chest tube drainage may be therapeutic and diagnostic, allowing fluid drainage and alleviation of symptoms of dyspnea. It will also allow determination of whether the underlying lung is able to expand. If not, it is described as a “trapped lung” and although the fluid may be gone, a persistent pneumothorax appears on chest x-rays as the lung cannot expand and fill the thorax. In these settings, an indwelling pleural drainage catheter may be the best option to intermittently drain accumulating fluid. Decortication is not recommended, as most patients with malignancy in this setting have a limited life expectancy and the success rate is low compared to decortication in the setting of an empyema. VATS exploration may also be used to remove loculated fluid collections and to evaluate for lung reexpansion after the procedure. If the lung reexpands, further treatment includes pleurodesis, utilizing talc, doxycycline, or bleomycin. These medications will cause an inflammatory reaction between the parietal and visceral pleura resulting in the lung being “stuck” in an expanded state.

Mechanical pleurodesis can also be performed by mechanical debridement of the pleura via VATS. Chemical pleurodesis may be performed via VATS or through an existing thoracostomy tube. The goal of treatment in the setting of a malignant pleural effusion is palliation.⁵³

Empyema

7 Empyemas are defined as frank pus in the thoracic cavity. This represents part of the continuum of disease that begins with simple parapneumonic effusion, where exudative fluid is not infected and not loculated. As the disease progresses, fluid becomes loculated with fibrinous septations and becomes infected, leading to pus and ultimately the development of a fibrinous peel. Upto half of pneumonias have an associated effusion, but less than 5% of cases lead to an empyema.⁵⁴ Other causes include surgical thoracotomies and/or other infections from nearby organs, such as esophageal injuries. Pleural infections have been categorized into three overlapping stages. The first is the exudative stage, where the fluid is thin, sterile, has a lower white blood cell (WBC) count and LDH levels, and the glucose level is still above 40 mg/dL (Table 80-6). Treatment usually involves addressing the underlying etiology, such as pneumonia. The second stage is the fibrinopurulent stage, where the fluid becomes infected and fibrin deposits accumulate on the pleura. The LDH and WBC count increases, the glucose and pH levels drop. The fluid becomes thick and purulent and the lung is often unable to expand. Chest tube drainage alone at this stage may not be effective to remove the fluid. The third stage is the organizing stage, and a thick pleural peel is created by migrating fibroblasts. At this point, a formal debridement and decortication is required to allow the lung to return to full function.⁵⁴

Figure 80-30. Schematic drawing of the most usual pattern and course of the thoracic duct. The single duct that enters the chest through the aortic hiatus between T12 and T10 is a relatively consistent finding and the usual site for surgical ligation.

Organisms causing empyemas have shifted from predominately *Streptococcus pneumoniae* in the preantibiotic era, to anaerobic organisms in upto three-quarters of empyemas in the current era. Imaging to evaluate the presence of an empyema begins with a simple chest x-ray, but requires a chest CT to show potential loculations. After the institution of antibiotic therapy, surgical intervention depends on the stage of the disease, but may require a VATS exploration or even a thoracotomy to debride the thorax effectively and to decorticate the pleural peel off of the lung to allow reexpansion.⁵⁴

Postpneumonectomy empyemas are an especially difficult problem as there is no lung tissue to occupy the empty thorax. Risk factors in this setting include right pneumonectomies (vs. left), the need for postoperative ventilation, lower starting hematocrit levels, and poor preoperative pulmonary function test results.^{55,56} Treatments of these empyemas are particularly difficult and may include an Eloesser flap or the Clagget procedure which allow for the creation of an open wound that allows for packing and granulation tissue to form in the empyema cavity.⁵⁷

Table 80-6 Diagnostic Criteria for Pleural Fluid in Empyema

Stage	Fluid/Peel	WBC	LDH (cells/mm ³)	pH (IU)	Bacteria
Exudative	Thin/elastic	<1,000	<500	>7.3	Absent
Fibrinopurulent	Purulent/inelastic	>5,000	>1,000	<7.1	Present
Organizing	Thick/rigid peel	Varies	Varies	<7.1	Varies

Mesothelioma

Malignant pleural mesothelioma (MPM) is a cancer of the serosal pleura, related to the exposure to asbestos. Multiple hypotheses have been formed regarding how asbestos causes mesothelioma, and include the idea that asbestos fibers are inhaled deeply into the lung and penetrate the parenchymal surface, causing irritation of the pleura and repeated episodes of inflammation, ultimately leading to cancer. Other potential mechanisms include asbestos interfering with mitosis, inducing free-radical production, and induction of protooncogene kinases by asbestos fibers.⁵⁸ Exposure to asbestos usually occurs decades prior to presentation with mesothelioma, and has been seen in miners exposed to asbestos dust, industrial workers such as plumbers and carpenters who used asbestos products, and even in 20% of patients with no known exposure but living in industrial countries. Mesothelioma is a relatively rare malignancy, with less than 5,000 cases in the United States per year.⁵⁹

Patients with mesothelioma may present with dyspnea or chest pain. Often, patients are asymptomatic and the diagnosis is made after abnormalities are seen on a chest x-ray performed for another reason. Radiographs may show unilateral effusions and a loss of volume on the affected side, as the lung capacity is diminished due to disease. As the disease progresses, patients may have weight loss, worsening pain, and night sweats. Median survival may be as little as 1 year from the time of diagnosis.⁶⁰ Diagnostic studies include a chest CT scan or MRI to show the extent of pleural thickening (Fig. 80-31). Lymphadenopathy or signs of local spread through the diaphragm or chest wall can also be seen with three-dimensional imaging. The pathologic diagnosis almost always requires a tissue biopsy. Cytologic examination of pleural fluid from a thoracentesis cannot differentiate between mesothelioma cells and other potential lung cancers. CT-guided biopsy of pleural thickening can often give the diagnosis, but ultimately a VATS approach or limited thoracotomy may be needed to obtain a diagnosis. If the patient is being considered for surgical resection, a limited thoracotomy in the site of a potential later incision is optimal to limit seeding of the tumor.⁶⁰

Mesotheliomas can be categorized into epithelial, sarcomatoid, and mixed histologies. Patients with epithelial histology do better than those with a sarcomatoid histology.⁶⁰ There are a variety of staging systems for mesothelioma, including the Butchart system, the revised Brigham and Women’s Hospital system, and the TNM-based system by the International Mesothelioma Interest Group (IMIG) (Table 80-7).^{60,61} The IMIG system allows for better reproducibility of the interpretation of local and regional lymph node spread. Laparoscopy may be useful to evaluate the patient for transdiaphragmatic spread of the tumor, differentiating between T3 and T4 tumors.⁶¹

Treatment for mesothelioma may include chemotherapy, radiation therapy, and surgery. Surgical treatment ranges from a pleurodesis for palliation in the setting of effusions and unresectable disease, to pleurectomy/decortication for limited disease, and to the most aggressive treatment of an extrapleural pneumonectomy (EPP), with the goal of complete tumor resection. Less than a third of patients are candidates for any surgical intervention. Preoperative workup for an EPP should include a cardiac evaluation, and optimal surgical candidates have pulmonary function tests with an FEV₁ of greater than 2 L/sec and an age under 70.⁶¹ Surgery involves an en bloc removal of the lung, pleura, pericardium and diaphragm with reconstruction of the pericardium and diaphragm. Pleurectomy and decortication is reserved for very early-stage disease and involves removal of the pleura only with preservation of the lung parenchyma. Multimodality approaches have shown better results, with neoadjuvant chemotherapy and adjuvant radiation therapy.⁶² Chemotherapy for advanced disease includes pemetrexed and cisplatin

or the combination of gemcitabine and cisplatin. Both have shown similar levels of palliation. Radiotherapy may also be used, but is limited by the large field requiring treatment and the risks of pneumonitis and esophagitis.⁵⁸ It is best used in combination with EPP for local control after surgery, or to treat local painful areas.⁶¹ Because of the rarity of surgical cases, most patients who are considered for surgery should be referred to high-volume centers where surgeons and other clinicians are comfortable treating this disease.

Figure 80-31. Magnetic resonance imaging of the patient in Figure 80-25 shows a large amount of tumor within the pleural space and into the diaphragmatic sulcus with no evidence of extension outside the hemithorax. (Reproduced with permission from Flores RM, Sugarbaker DJ. Malignant mesothelioma of the pleural space. *Ann Thorac Surg* 2000;70:306.)

STAGING

Table 80-7 The International Mesothelioma Interest Group (IMIG) Staging System

T-Tumor		
T1	1a	Tumor limited to the ipsilateral parietal pleura, including mediastinal and diaphragmatic pleura; noninvolvement of the visceral pleura
	1b	Tumor involving the ipsilateral parietal pleura, including mediastinal and diaphragmatic pleura; scattered foci of tumor also involving the visceral pleura
T2		Tumor involving each of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following features: Involvement of diaphragmatic muscle Confluent visceral pleural tumor (including the fissures) or extension of tumor from visceral pleura into the underlying pulmonary parenchyma
T3		Locally advanced but potentially resectable tumor; tumor involving all of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following features: Involvement of the endothoracic fascia Extension into the mediastinal fat Solitary, completely resectable focus of tumor extending into the soft tissues of the chest wall Nontransmural involvement of the pericardium
T4		Locally advanced technically unresectable tumor; tumor involving all of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral) with at least one of the following features: Diffuse extension or multifocal masses of tumor in the chest wall, with or without associated rib destruction Direct transdiaphragmatic extension of tumor to the peritoneum Direct extension of tumor to the contralateral pleura Direct extension of tumor to one or more mediastinal organs Direct extension of tumor into the spine Tumor extending through to the internal surface of the pericardium with or without pericardial effusion; or tumor involving the myocardium

N–Lymph Nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Metastases in the ipsilateral bronchopulmonary or hilar lymph nodes
N2	Metastases in the subcarinal or ipsilateral mediastinal lymph nodes, including the ipsilateral internal mammary nodes
N3	Metastases in the contralateral mediastinal, contralateral internal mammary, ipsilateral or contralateral supraclavicular lymph nodes
M–Metastases	
MX	Presence of distant metastases cannot be assessed
M0	No distant metastasis
M1	Distant metastasis present
Stage	Description
I	
Ia	T1aN0M0
Ib	T1bN0M0
II	T2N0M0
III	Any T3M0 Any N1M0 Any N2M0
IV	Any T4 Any N3 Any M1

Trachea

The trachea is a well-known structure to the general surgeon who may perform tracheostomies and bronchoscopies as part of their clinical practice. A thorough knowledge of the anatomy and vascular supply is essential to minimize complications such as postintubation tracheal stenosis and tracheoinnominate fistulas after tracheostomies.

Anatomy

The trachea is the connection from the cricoid cartilage to the carina that allows ventilation and mucous clearance from the lungs. It is oval shaped, with C-shaped cartilaginous rings creating the anterior and lateral borders. A soft tissue membrane forms the posterior wall to complete the oval shape. In the average male, the anterior–posterior dimension is 1.8 cm, while the lateral aspect is 2.3 cm. Tracheal length reaches almost 12 cm with almost 2 rings per centimeter. Tracheae in women are 10% to 20% smaller in size. In children, the shape is more circular, but becomes gradually more ovoid as people age. There is a significant amount of flexibility in the normal trachea, and remodeling can occur in chronic disease states such as emphysema. The inner lining consists of ciliated pseudostratified columnar epithelium with goblet and mucous cells interspersed. At the carina, the right and left mainstem bronchi split off. The right side is characterized by the quick takeoff of the right upper-lobe bronchus, with the bronchus intermedius continuing into the middle and lower-lobe bronchi. The left side has a longer mainstem bronchus with a split into the upper and lower lobes.⁶³ The blood supply begins with the inferior thyroid artery supplying the cervical trachea through three tracheoesophageal branches. The lower trachea is supplied by bronchial arteries arising off the aorta. As the arteries approach the trachea, they further split to supply separate segments. Even within segments, it will branch into anterior and posterior transverse intercartilaginous arteries (Fig. 80-32). Because of this segmental blood supply, there should be minimal circumferential dissection around the trachea to limit impairment of the blood supply and healing in tracheal/bronchial surgery.

Figure 80-32. Semischematic view of the tracheal microscopical blood supply. Transverse intercartilaginous arteries derived from the lateral longitudinal anastomosis penetrate the soft tissues between each cartilage to supply a rich vascular network beneath the endotracheal mucosa.

Surgical Airways

The most common tracheal procedure is a tracheostomy. Over the last 20 years, there has been an increasing utilization of percutaneous tracheostomy. For patients who are intubated, the indication for and timing of tracheostomy depends on a multitude of factors, of which there is very little consensus in the medical literature. The goal of a tracheostomy is to limit the risk of laryngeal stenosis caused by prolonged endotracheal intubation, to improve pulmonary toilet, and to improve oral hygiene. Generally, tracheostomy should be considered after a patient has been intubated for more than 7 days, without clear expectation for immediate extubation.⁶⁴ Ideally, patients should be on minimal ventilator settings, but tracheostomy may be performed in patients with elevated oxygen (FiO_2 of upto 60%) and ventilatory (PEEP under 10) requirements. Patients requiring more support are at high risk of decompensating if they lose their airways, even if just for a moment, and the decision to perform a tracheostomy should be carefully considered in this setting.⁶⁵

Tracheostomies are performed with the neck extended. A 2- to 3-cm incision is made approximately 2 cm above the sternal notch. Dissection is carried down through the platysma, and the strap muscles are divided longitudinally. Exposure of the trachea and the 2nd and 3rd rings may require elevation of the thyroid. Lateral traction sutures may be placed around the 2nd or 3rd rings. A vertical incision is made between rings 2 and 4 and gradually dilated. A tracheostomy tube is placed under direct vision.^{64,66} Percutaneous tracheostomy placement is based on the Seldinger technique. A needle is placed percutaneously into the trachea at the estimated level of the 2nd or 3rd rings with bronchoscopic visualization. A guidewire is placed into the airway, and serial dilations performed, until a tracheostomy tube is able to be advanced over the wire.⁶⁵ Cricothyroidotomy should only be performed in the emergent setting. The cricothyroid membrane is palpated below the superior thyroid notch. A transverse incision is made to the lateral borders of the thyroid cartilage. Rapid dilation is followed by tube insertion.⁶⁴

Complications can vary depending on the technique. For open tracheostomy, they include damage to the carotid artery, internal jugular vein, the posterior tracheal wall/anterior esophagus, and to the apex of the lung.⁶⁵ Also reported are fires due to the use of electrocautery in the setting of nitrous oxide and oxygen.⁶⁴ In percutaneous tracheostomies, complications include pneumothorax, mediastinal emphysema, paratracheal insertion, tracheoesophageal fistula, and airway loss.^{65,67} Common complications include local hemorrhage and infection. Major late complications include tracheal stenosis and tracheoinnominate fistulas. Fistulas result from erosion of the tracheostomy tube into the innominate artery. Improper placement of the tracheostomy into rings lower than the 3rd ring place patients at higher risk for this complication. A sentinel bleed may be the initial presentation. Pressure on the fistula with immediate repair or ligation of the vessel is required (Fig. 80-33).⁶⁸ Postintubation stenosis is usually due to necrosis caused by high-pressure cuffs resulting in impaired blood flow to the segmental area of the trachea. This leads to the long-term loss of cartilage and narrowing of the airway. The use of low-pressure cuffs has reduced the incidence of this complication, but not eliminated it. Bronchoscopy and dilation may alleviate symptoms, but resection of the stenotic area may be needed (Fig. 80-34).⁶⁶

Tracheal Tumors

Benign lesions of the trachea are less common than malignant ones. They include papillomas,

chondromas, hamartomas, fibromas, and hemangiomas. Papillomas are associated with the human papilloma virus and can degenerate into malignant lesions, thus requiring resection. Chondromas arise from the cartilage, and may recur after resection. Hamartomas are comprised of cartilage, epithelial and lymphatic tissue. Recurrence is rare after resection. Fibromas can be resected via bronchoscopy. Hemangiomas are the most common pediatric tracheal mass. They may regress without treatment and can be observed if not causing obstructive symptoms. Biopsy is general avoided due to bleeding risk. Surgery may be required if lesions persist.⁶⁹

Figure 80-33. Management of tracheoinnominate artery fistula. **A:** Common mechanism of injury from erosion of innominate artery by adjacent tracheostomy tube. **B:** Emergency treatment of hemorrhage involves insertion of an endotracheal tube into the tracheostomy stoma, inflation of the cuff, and downward and outward pressure on the fistula by the finger inserted through the tracheostomy incision to further tamponade the bleeding. **C:** Through a partial upper sternal split, the segment of involved innominate artery is resected and the oversewn ends covered with adjacent mediastinal fat or muscle. Tracheal resection is usually not necessary. A new tracheostomy tube may have to be inserted higher in the trachea or, if possible, the tracheostomy tube removed and the stoma covered with a sternohyoid muscle flap.

Although more common than benign lesions, malignant tracheal tumors are very rare with only 600 to 700 cases in the United States per year. Lesions may be primary tracheal lesions, tumors from

adjacent organs growing into the trachea, or metastatic lesions.⁷⁰ Primary tumors are most commonly squamous cell carcinomas or adenoid cystic carcinomas in the trachea, followed by carcinoids in the bronchi.^{70,71} Adjacent tumors may arise in the lung, esophagus, thyroid, or mediastinum. The most common cancers that cause tracheal metastases include renal cell cancers, sarcomas, breast cancers, and colon cancers.⁷⁰ Patients will present with stridor and wheezing, and have often been recently diagnosed with adult-onset asthma and treated with inhalers and even steroids without alleviation of symptoms. Hemoptysis may also occur, though it is more common in lung cancer than in tracheal disease.⁷¹ Patients should undergo imaging such as a neck and chest CT scan to assist in making the proper diagnosis. Bronchoscopy with a flexible or rigid endoscope is essential to aid in the evaluation of the extent of disease and to control the airway if necessary. Treatment includes tracheal resection for primary tumors if possible. For metastatic disease, palliative treatment include endoluminal resection and/or radiotherapy.⁷¹ Endoluminal treatments include mechanical core-out, YAG-laser treatment, photodynamic therapy (PDT), cryotherapy, or brachytherapy. Stenting also may play a role to maintain airway patency, either for a temporary period during radiation treatment, or in the setting of end-stage disease ([Algorithm 80-5](#)).⁷⁰

Figure 80-34. Diagrams of principal postintubation tracheal lesions. **A:** Cuff stenosis from the cuff of an endotracheal tube. **B:** Cuff stenosis from the cuff of a tracheostomy tube, usually lower in the trachea than that from an endotracheal tube. Stomal stenosis also occurs at the site of the tracheostomy itself. Malacia may occur either at the level of the cuff or in the segment between the stoma and the cuff stenosis. **C:** Cuff stenosis at the site of a high tracheostomy stoma, which has eroded into the lower margin of the cricoid cartilage. In older patients, this may erode back farther into the subglottic larynx, producing a laryngotracheal stenosis. A stoma placed in the cricothyroid membrane will, by definition, produce an intralaryngeal stenosis. **D:** Tracheoesophageal fistula (TEF) produced by pressure of the cuff against the “party wall,” often abetted by an indwelling firm nasogastric tube. **E:** One type of tracheoinnominate fistula (TIF) as the result of a high-pressure cuff erosion. The more common type, but also rare, is that seen with a low-placed tracheostomy stoma, which rests against the innominate artery itself. (Reproduced with permission from Grillo HC. Surgical treatment of postintubation tracheal injuries. *J Thorac Cardiovasc Surg* 1979;78:860–875.)

Tracheomalacia and Airway Stents

Tracheomalacia occurs when the trachea loses its rigid form and the posterior membranous wall approaches the anterior wall, causing luminal narrowing and obstruction leading to dyspnea. Patients have a characteristic seal-like cough. Chest CT scans may demonstrate this condition, and pulmonary function testing in these patients will show reduced FEV₁, FVC and peak expiratory flow rates. Bronchoscopy is the best diagnostic test and reveals real-time airway collapse with expiration. Etiologies include congenital tracheomalacia, extrinsic compression, postintubation stenosis and inflammation, relapsing polychondritis, and COPD.⁷² Surgical intervention may include resection for localized involvement, tracheoplasty, or stenting.^{72,73} Airway stents can be divided into two groups, silicone and metal, with each type having distinct advantages ([Table 80-8](#)). Silicone stents require rigid bronchoscopy to place, have a narrower inner lumen, and are more easily displaced. Advantages to the use of silicone stents are that they are easily adjustable or removable, they do not develop tissue ingrowth, and they are nonreactive to the endoluminal lining. Metal stents can be placed by flexible bronchoscopy and conform to the trachea better. They are permanent and difficult to adjust. Placement requires fluoroscopy, and granulation tissue often grows in between metal struts making subsequent removal difficult.⁷⁰ Newer stents being developed include covered metal stents that prevent tumor in growth along the stent, but unfortunately still allow granulation tissue to grow in at the ends.⁷⁴ In

addition to being useful in the setting of tracheal stenosis, they can also play an essential role in palliating posttransplant bronchial stenosis.⁷⁵

Algorithm 80-5. Algorithm for management of tracheal masses. (Adapted from Wood DE. *Surg Clin North Am* 2002;82(3):621–642.)

Table 80-8 Classification of Airway Stents

■ Silicone stents
Advantages
Adjustable
Removable
Minimal granulation
Disadvantages
Gen. anesthesia/rigid bronch to place
Migrates
Secretions adhere to stent
Interferes with ciliary clearance
Smaller inner diameter
■ Metal stents
Advantages
Less migration
Larger inner diameter
Less ciliary interference
Flexible bronch to place
Disadvantages
May need balloon dilation
Difficult to remove
Granulation and tumor ingrowth in the stent
Radial force may lead to necrosis/fistula

Mediastinum

The mediastinum contains a number of important structures and may be involved in different disease processes. Mediastinal infections are not as common as they were in the past, but when they present, they are life-threatening situations. The mediastinum is divided into several compartments, including the superior, anterior, middle, and posterior regions. Sometimes the lower three compartments are extended superiorly and only three are described (Fig. 80-35). The anterior mediastinum includes the fat and lymph nodes posterior to the sternum, but anterior to the pericardium. The middle compartment includes the pericardium, heart, aorta, and trachea. The posterior compartment includes the esophagus, sympathetic chain, and vertebral column (Fig. 80-36). Most lesions are found in asymptomatic patients, but presenting symptoms include dyspnea and chest pain. Symptoms may be local, related to compression on mediastinal structures, or systemic, caused by the release of cytokines or inflammatory factors, such as in lymphomas or thymomas with myasthenia gravis (MG). Imaging begins with plain radiographs, but CT scans are essential. MRI scans may be helpful to evaluate vascular or spinal involvement. PET scans are increasingly utilized as they may further aid in staging. Biopsy and/or surgical resection is required to confirm the diagnosis in almost all patients.⁷⁶

Figure 80-35. The mediastinal subdivisions. Note that the paravertebral sulcus encompasses the posterior compartment. Reproduced with permission from Shields TW, ed. *General Thoracic Surgery*. 6th ed. 2005.

Anterior Mediastinum

The anterior mediastinum can contain a variety of tumors ([Table 80-9](#)). Most common are thymomas, lymphomas, and germ cell tumors, in that order. Thymomas account for one-fifth of all anterior mediastinal masses in the adult population. They arise from the thymus gland and can be seen with autoimmune diseases such as MG and pure red cell aplasia. Tumors are usually classified by the Masaoka classification system ([Table 80-10](#)), which looks at gross and microscopic spread of the tumor, or the World Health Organization (WHO) histologic criteria, which is based upon the morphology of the epithelial cells as well as the lymphocyte to epithelial cell ratio. Diagnosis is usually made by chest CT scan. Needle biopsy of a potential thymoma is not routinely recommended for fear of seeding the needle track. When thymomas are suspected, resection is the best option, via a midline sternotomy ([Fig. 80-37](#)). Resection must take care to remove all of the tissue in the anterior compartment, including all fat and tissue around the innominate vein. Entering the pleura should be avoided if possible to minimize drop metastases into either pleural space.

RULB, right upper-lobe bronchus; LMB, left mainstem bronchus; AA, ascending aorta; DA, descending aorta; A, azygos vein; PA, main pulmonary artery; LPA and RPA, left and right pulmonary arteries. **C:** Scan at the level of the left atrium. LA, left atrium; RA, right atrium; LVOT, left ventricular outflow tract; RV, right ventricle.

Table 80-10 Masaoka Staging System for Thymoma

Stage	Definition
I	Macroscopically, completely encapsulated; microscopically, no capsular invasion
IIA	Macroscopic invasion in surrounding fatty tissues or mediastinal pleura
IIB	Microscopic invasion into the capsule
III	Macroscopic invasion into a neighboring organ, such as pericardium, great vessels, or lung
IVA	Pleural or pericardial dissemination
IVB	Hematogenous or lymphogenous metastases

Adapted from Masaoka A, Monden Y, Nakahara K, et al. Follow-up study of thymomas with special references to their clinical stages. *Cancer* 1981;48:2485, with permission.

Thoracoscopic approaches to resect thymomas have been described, but some surgeons question this approach due to the potential increased risk of drop metastases, and thus the potential for a poorer oncologic outcome. Neoadjuvant chemotherapy and radiation may be used to downstage Masaoka III and IV stage tumors and allow for subsequent resection. Postoperative radiation is recommended for Masaoka stage III tumors, and may be considered for stage II disease. Platinum-based chemotherapy is typically utilized in the unresectable setting.⁷⁷ MG presents with diplopia, ptosis, fatigue, and weakness. One-third to one-half of patients with thymomas have MG, but only 10% of patients with MG have thymomas. Antiacetylcholine receptor antibody levels may be measured to evaluate for MG in patients with suspected thymomas.⁷⁸ Thymic carcinomas and thymic carcinoids are other tumor types that can also arise from the thymus.

Germ cell tumors can present as benign teratomas, seminomas, and embryonal tumors, which include nonseminomatous germ cell tumors and malignant teratomas. Benign teratomas have a good prognosis and resection is the best treatment. Seminomas comprise up to half of mediastinal germ cell malignant tumors. Patients may have symptoms from local compression or systemic symptoms such as fever, weight loss, and even gynecomastia. These tumors are radiosensitive, but in locally advanced disease, chemotherapy with later surgical resection is the favored treatment. Nonseminomatous tumors include a wide variety of histologic malignancies. They usually occur in young men and are often symptomatic (Fig. 80-38). Elevated alpha-fetal protein (AFP) and beta-human chorionic gonadotropin (β -hCG) levels are seen with these tumors and should be measured. Chemotherapy is the best treatment, but patients have a poorer prognosis when compared to those with seminomas. Lymphomas in the mediastinum are usually part of a wider spectrum of disease. Two-thirds of cases are Hodgkin disease. Most patients present with symptoms of fevers, night sweats, and even weight loss. Treatment is always chemotherapy-based, and surgery in the form of a biopsy is utilized only to help make the diagnosis.⁷⁸

Figure 80-37. Thymic resection. **A:** Exposure of thymus via median sternotomy. **B:** Elevation of thymus completely off of the pericardium. **C:** Pulling the thymus inferiorly to resect the right superior horn (and later the left superior horn). Computed tomography scan reveals a bronchogenic cyst located in the subcranial area with compression of the left mainstem bronchus with hyperinflation of the left lung and a mediastinal shift to the right. (Reproduced with permission from Shields TW. Primary lesions of the mediastinum and their investigation and treatment. In: Shields TW, ed. *General Thoracic Surgery*. Baltimore, MD: Williams & Wilkins; 1994:1764–1769.)

Middle and Posterior Mediastinum

Middle mediastinal masses include esophageal and bronchogenic cysts, pericardial cysts, lymphangiomas, and lymphomas (Fig. 80-39). For cystic lesions, surgical resection is the best treatment option. Posterior lesions include neurogenic tumors which may be benign or malignant. Almost 95% of tumors come from the sympathetic chain or intercostal nerve rami. Upto two-thirds of these tumors are benign nerve sheath tumors and are usually discovered incidentally. A MRI scan may be used to evaluate intraspinal extension.⁷⁸

Pediatric Mediastinum

The presentation of mediastinal masses in the pediatric population varies from what is observed in adults. The rate of malignancy is slightly lower in children, and while thymomas are the most common adult masses seen, neurogenic tumors are more common in children (Table 80-11). Just over half of all mediastinal tumors arise in the posterior compartment.⁷⁹ Anterior masses may include the normal thymus in a young child. Teratomas are the most common germ cell tumor seen.⁷⁹ Vascular anomalies may be seen in children and include hemangiomas and cystic hygromas.⁸⁰ Middle compartment tumors are usually foregut cysts, as in the adult population. Posterior tumors are most often malignant neurogenic tumors, compared to more benign pathology in adults.⁷⁹

Mediastinitis

9 Mediastinal inflammation can arise from different sources, but it is most often infectious in nature.

Acute mediastinitis is life-threatening and usually results from a perforated esophagus, postcardiac procedure, or trauma. Oral infections can also result in organisms travelling through the neck into the mediastinum along fascial planes. These infections can travel as quickly as necrotizing fasciitis does in other parts of the body and should be addressed immediately. A wide variety of organisms can cause mediastinitis. Patients will have chest pain, dyspnea, and fevers. Radiographic films may show pneumomediastinum or pneumothoraces. If an esophageal perforation is suspected, an esophagogram should be performed. Treatment is broad-spectrum antibiotics and surgical drainage via a cervical incision and/or thoracotomy. Quick debridement and drainage are keys to patient survival. Minimally invasive approaches to the chest may be adequate, but surgeons should have a low threshold to perform a posterolateral thoracotomy, which may give the best exposure and opportunity to debride the chest. Sternal infections after cardiac surgery can also be a serious problem requiring drainage and debridement. Ultimate repair of the defect following debridement may involve muscle or omental flaps for sternal reconstruction.

Table 80-11 Mediastinal Tumors in Children

Type of Tumor	Incidence Reported in Series (%)
Neurogenic	35
Lymphoma	25
Germ cell	11
Primary malignancy	2
Cysts	25

Adapted from Davis RD Jr, Oldham HN Jr, Sabiston DC Jr. The mediastinum. In: Sabiston DC Jr, Spencer FC, eds. *Surgery of the Chest*. 5th ed. Philadelphia, PA: WB Saunders; 1990:507.

Chronic mediastinitis is a separate entity from acute mediastinitis and may arise from infectious sources or autoimmune disorders. Patients may be asymptomatic until a mass effect is seen on their mediastinal organs. CT scans are the best imaging modality to diagnose this condition, and surgery is reserved only for diagnosis or in the end stages of the disease to relieve compression on other organs. Sclerosing mediastinitis may be seen in patients with retroperitoneal fibrosis.⁸¹

Superior Vena Cava Syndrome

Superior vena cava (SVC) syndrome is a rare condition seen when a mediastinal mass compresses the SVC resulting in facial and upper body edema. Only 15,000 cases per year are seen in the United States. Patients may present with cough, dyspnea, or even stridor from upper airway edema. When patients start to have symptoms, collateral venous drainage develops to drain into the azygos vein or inferior vena cava. This process usually takes weeks. Malignant tumors are the most common cause, but venous thrombosis and nonmalignant lesions cause upto one-third of cases. CT scans are the best diagnostic test. Treatment is based on supportive care and addressing the underlying condition causing the obstruction. If a malignant tumor is causing the obstruction, chemotherapy or radiotherapy may shrink the tumor and lessen symptoms. Surgical resection with SVC reconstruction may be used in specific tumors such as locally advanced thymomas. Angioplasty and stenting may be of benefit but is usually palliative.⁸² Although it is often felt to be an emergency, most cases of SVC syndrome have a slowly progressive course. When a patient develops symptoms, supportive care, including possible intubation, will allow time for collateral venous drainage to develop and symptoms to improve without other interventions. Although the median survival is typically 6 months or less in patients with SVC syndrome from malignant obstruction, some have seen long-term survivors when the primary tumors have responded to appropriate treatment.⁸³ When patients present with severe symptoms, it is a mistake to rush to surgical intervention without a long-term plan. Symptoms should be managed and the etiology discovered and treated appropriately.

SECTION M: VASCULAR DISEASE

Chapter 81

Congenital Heart Disease

Jennifer C. Hirsch-Romano, Richard G. Ohye, and Edward L. Bove

Key Points

- 1 The first successful treatment of a congenital lesion was the closure of a patent ductus arteriosus (PDA) by Gross and Hubbard in 1938. Prostaglandin inhibitors, such as indomethacin and ibuprofen, can be used to induce closure of a PDA in the premature newborn with a success rate of 80%. When this is not successful, surgical closure may be necessary in small infants. Coil occlusion can be performed in older children presenting with a PDA.
 - 2 An atrial septal defect (ASD) is a hole in the atrial septum. ASDs are the third most common congenital heart defect, occurring in 1 out of 1,000 live births and representing 10% of congenital heart defects. ASDs cause right heart volume overload and can lead to pulmonary vascular obstructive disease later in life. The majority of ASDs are now closed with a device in the catheterization laboratory.
 - 3 Ventricular septal defects (VSDs) are the most common congenital heart defect (with the exception of bicuspid aortic valve, which occurs in about 1.3% of the population). VSDs cause left heart volume overload.
 - 4 Over 50% of children with trisomy 21 have a congenital heart defect. The most common heart defect in this patient population is an atrioventricular septal defect. All infants with trisomy 21 should have an echocardiogram to rule out congenital heart disease.
 - 5 Tetralogy of Fallot (TOF) is the most common cyanotic congenital heart defect. It occurs in 0.6 per 1,000 live births and has a prevalence of about 5% among all patients with congenital heart disease. The pathologic anatomy is frequently described as having four components: ventricular septal defect, overriding aorta, pulmonary stenosis, and right ventricular hypertrophy.
 - 6 Transposition of the great arteries is a congenital cardiac anomaly in which the aorta arises from the right ventricle and the pulmonary artery originates from the left ventricle (ventriculoarterial discordance). It is the most common congenital heart defect presenting with cyanosis in the first week of life. This malformation accounts for approximately 10% of all congenital cardiovascular malformations in infants.
 - 7 Upper extremity hypertension with diminished femoral pulses are hallmark clinical findings in patients with aortic coarctation.
 - 8 Coronary arteriovenous fistula is the most common major coronary anomaly.
-

HISTORY

Cardiac surgery, as a specialty, is notable for the rapid technical advances that have been made during the past few decades. Much of the original interest was focused on attempts to treat congenital heart defects associated with cyanosis and early mortality. 1 The first successful treatment of a congenital lesion was the closure of a patent ductus arteriosus (PDA) by Gross and Hubbard in 1938.¹ The description of the subclavian artery-to-pulmonary artery (PA) shunt by Blalock and Taussig in 1945² introduced the palliation of many complex cyanotic lesions – most notably, tetralogy of Fallot (TOF). The 1950s represented the decade of greatest advances, which laid the foundation for the field of cardiac surgery. Lewis and Taufic in 1952³ performed the first open closure of an atrial septal defect (ASD) by using surface hypothermia and inflow occlusion. In 1953, Gibbon⁴ performed the first repair of an ASD with the use of a pump oxygenator that became the model for modern cardiopulmonary bypass. Next, Warden et al.⁵ used controlled cross-circulation with an adult as the oxygenator during intracardiac repairs. Building on the work of Gibbon, Kirklin et al.⁶ then published the first series of eight intracardiac operations performed at the Mayo Clinic with the use of cardiopulmonary bypass.

With these landmark efforts focused on congenital heart disease, the field of cardiac surgery was established.

ATRIAL SEPTAL DEFECT

Cardiac septation occurs between the third and sixth weeks of fetal development. The septum primum, which arises from the roof of the common atrium and descends inferiorly, initially divides the common atrium. The ostium primum is the opening below the inferior edge of the septum primum, which is obliterated as the septum primum fuses with the endocardial cushions. The ostium secundum forms in the midportion of the septum primum prior to closure of the ostium primum. The septum secundum also arises from the roof of the atrium and descends along the right side of the septum primum and covers the ostium secundum. This creates a flap valve whereby blood from the inferior vena cava may preferentially stream beneath the edge of the septum secundum and through the ostium secundum into the left atrium. After birth, the increase in left atrial pressure usually closes this pathway.

2 An ASD is a hole in the atrial septum (Fig. 81-1). ASDs are the third most common congenital heart defect, occurring in 1 out of 1,000 live births and representing 10% of congenital heart defects.⁷ The most common ASD is the secundum defect, which occurs when the ostium secundum is too large for complete coverage by the septum secundum. Ostium secundum defects account for about 80% of ASDs. An ostium primum ASD, representing 10% of ASDs, occurs from failure of fusion of the septum primum with the endocardial cushions. The ostium primum defect is discussed later in the section on atrioventricular septal defects (AVSDs). A third type of ASD is the sinus venosus defect, seen in about 10% of cases. Sinus venosus ASDs are caused by abnormal fusion of the venous pathways with the atrium and are characterized by defects high in the atrial septum near the orifice of the superior vena cava or, less commonly, low in the atrial septum near the inferior vena cava. Sinus venosus defects are frequently associated with partial anomalous pulmonary venous connection, usually with the right upper pulmonary vein draining into the superior vena cava near the cavoatrial junction. The rarest type of ASD is the unroofed coronary sinus septal defect. This occurs when there is loss of the common wall between the coronary sinus and the left atrium adjacent to the atrial septum. This unroofing of the coronary sinus leads to a communication between the right and left atria at the site of the coronary sinus.

Figure 81-1. The anatomy of atrial septal defects. In the sinus venosus type (A), the right upper and middle pulmonary veins frequently drain to the superior vena cava or right atrium. B: Secundum defects generally occur as isolated lesions. C: Primum defects are part of a more complex lesion and are best considered as incomplete atrioventricular septal defects.

Failure of postnatal fusion of the septum secundum to the septum primum results in a persistent slit-like communication known as a patent foramen ovale (PFO). PFOs are extremely common in the general population, and autopsy studies have demonstrated a prevalence of 27%.⁸ PFOs are generally considered separate from other ASDs due to the absence of significant shunting, but they remain important clinically due to the occurrence of paradoxical embolization. A paradoxical embolus is a blood clot arising from a systemic vein that would normally pass to the lungs, but in the presence of a septal defect, may instead cross into the systemic circulation.

ASDs lead to increased pulmonary blood flow (PBF) secondary to left-to-right shunting. Shunting at the atrial level is determined by the size of the defect and by the relative ventricular compliance (i.e., blood preferentially fills the more compliant ventricle). At birth, both chambers are equally compliant, but as pulmonary vascular resistance (PVR) falls, the right ventricle remodels and becomes more compliant. Shunting across the atrial septum causes a volume load on the right heart. A volume load is created by additional venous return to a chamber during diastole.

The volume overload from an ASD is usually well tolerated, and patients are frequently asymptomatic. Symptoms tend to develop when the ratio of pulmonary to systemic blood flow (Q_p/Q_s) exceeds two. The most common symptoms are fatigue, shortness of breath, exercise intolerance, and recurrent respiratory infections. Older patients with untreated ASDs tend to develop atrial dysrhythmias, and adults may develop congestive heart failure (CHF) and right ventricular dysfunction. Pulmonary vascular obstructive disease may occur rarely as a late complication of an untreated ASD. Paradoxical embolization is also an important potential complication of an ASD.

The classic physical findings in patients with ASDs include fixed splitting of the second heart sound and a systolic ejection murmur at the left upper sternal border due to relative pulmonary stenosis (PS) (increased flow across a normal pulmonary valve). A diastolic flow murmur across the tricuspid valve is occasionally audible. A prominent right ventricular lift and increased intensity of the pulmonary component of the second heart sound may occur with pulmonary hypertension. Chest radiography shows cardiomegaly, with enlargement of the right atrium, right ventricle, and pulmonary artery. Electrocardiography (ECG) frequently demonstrates right axis deviation and an incomplete right bundle branch block. When right bundle branch block occurs with a leftward or superior axis, the diagnosis of AVSD should be considered. Echocardiography confirms the diagnosis of ASD and defines the anatomy. Cardiac catheterization is important in selected cases to assess PVR in older patients, but it is used more frequently with therapeutic intent for device closure of ASDs.

Due to the long-term complications associated with ASDs, repair is recommended for all patients with symptomatic defects and in asymptomatic patients in whom the Q_p/Q_s is greater than 1.5 or signs of right heart enlargement. Repair is usually performed in children prior to school age. Closure of ASDs may be performed surgically or using a device deployed in the cardiac catheterization laboratory.

Surgical repair is usually recommended for large secundum defects and for most other types of ASDs. The heart is exposed by median sternotomy. Other surgical approaches have been proposed, including minimally invasive techniques, but there are technical drawbacks associated with each of the alternative approaches. In most cases, a limited midline incision with a partial lower sternal split provides adequate exposure and a cosmetically acceptable scar. The heart is carefully inspected for anomalies of systemic and pulmonary venous return.

Cardiopulmonary bypass is required with minimal cooling. The superior and inferior vena cava are separately cannulated for venous drainage, and the arterial cannula is placed in the ascending aorta. Following aortic clamping and arrest of the heart with cardioplegia, the atrial septum is exposed through a right atriotomy. Small secundum defects or PFOs may sometimes be closed primarily by suturing the edge of the septum primum to the edge of the septum secundum. More commonly, larger defects are closed using a patch (polytetrafluoroethylene or autologous pericardium) and a running polypropylene suture. When anomalous pulmonary venous drainage is present, a baffle is created to redirect the flow across the ASD. In all cases, care is taken to de-air the left atrium to avoid the complication of air embolization. Surgical closure of an ASD can be accomplished with a mortality approaching zero and minimal morbidity.⁹ Common postoperative complications include atrial arrhythmias and postpericardiotomy syndrome.

The first transcatheter device closure of an ASD was performed in 1976.¹⁰ A number of devices are currently available for percutaneous closure of secundum ASDs.¹¹ The contemporary success rate for device deployment is 96% with complete closure at 24 hours of 99% or greater.^{12,13} The presence of a deficient rim is the most common reason for failed implantation.¹³ Device closure has the advantages of fewer complications and a shorter hospitalization. Device closure of small to moderate secundum ASDs and PFOs has now become the standard of care at most large centers. Surgical closure remains the procedure of choice for large or multiple defects, insufficient rims, sinus venous-type defects, and primum ASDs.

The long-term survival for patients undergoing ASD repair in childhood is normal.^{14,15} The major long-term complication following surgical closure of ASD is the development of supraventricular arrhythmias, although the risk is lowered when the ASD is closed in childhood.^{15,16} The persistence of this risk despite relief of right-sided volume overload is thought to be related to incomplete atrial remodeling or due to the presence of the atriotomy scar. Longer follow-up will be required to determine whether device closure alters the risk of atrial dysrhythmias.

Occasionally, adults will present with a newly diagnosed ASD. Many studies have confirmed that ASD closure in adults over the age of 40 increases survival and limits the development of heart failure.^{17,18} When the Q_p/Q_s is less than 1.5 and the ratio of pulmonary to systemic vascular resistance (R_p/R_s) is greater than 0.7, significant pulmonary vascular obstructive disease is usually present. A PVR in excess of 10 to 12 Woods units/ m^2 represents a contraindication to ASD closure.

VENTRICULAR SEPTAL DEFECT

Ventricular septation is a complex process that requires accurate development and alignment of a number of structures including the muscular interventricular septum, the atrioventricular (AV) septum

(arising from the endocardial cushions), and the infundibular septum (which divides the outflow tracts of the right and left ventricles). The membranous septum is a fibrous portion of the ventricular septum that is adjacent to the central fibrous body (where the mitral, tricuspid, and aortic valve annuli make contact).

3 Ventricular septal defects (VSDs) are the most common congenital heart anomalies (with the exception of bicuspid aortic valve, which occurs in about 1.3% of the population). VSDs are present in about 4 of 1,000 live births and represent about 40% of congenital heart defects.⁷ VSDs are classified based on their location in the ventricular septum (Fig. 81-2). The most common defects are perimembranous (80%), which are located in the area of the membranous septum. Inlet defects (5%) are located beneath the septal leaflet of the tricuspid valve and are sometimes called AV canal-type defects. Defects located high in the ventricular septum are outlet defects (10%). Outlet VSDs are typically adjacent to both the pulmonary and aortic valves. Outlet defects are also known by several other names, including supracristal, infundibular, or doubly committed subarterial. Outlet defects are more common in the Asian population. Trabecular (or muscular) VSDs (5%) are completely bordered by muscle. Trabecular VSDs are frequently multiple and may be associated with perimembranous or outlet defects. The size of VSDs varies. By definition, a VSD is nonrestrictive when its size (or the cumulative size of multiple defects) is greater than or equal to the size of the aortic annulus.

Figure 81-2. The anatomy of ventricular septal defects (VSDs) as seen through the right ventricle. **A:** Outlet, or subarterial, VSDs are generally bordered superiorly by the pulmonary valve annulus. **B:** Perimembranous VSDs are most common, extending from the membranous septum into the infundibular septum. **C:** Inlet defects are located predominantly beneath the septal leaflet of the tricuspid valve. **D:** Muscular VSDs are situated away from the valves, toward the cardiac apex.

A VSD causes increased PBF due to left-to-right shunting primarily during systole. This creates a volume load on the left heart (the left atrium and ventricle receive the increased venous return during diastole). The right ventricle is not volume loaded (blood is ejected from the left ventricle [LV] through the VSD and directly into the pulmonary circulation); however, it does experience a pressure load. The volume of shunt flow is determined by the size of the defect and by the ratio of pulmonary to systemic vascular resistance. After birth, the PVR is still high and shunting across a VSD is sometimes minimal. Over the first several weeks of life, shunting tends to increase as the PVR normally falls. Therefore, a

patient with a large VSD may be asymptomatic at birth and develop severe CHF symptoms over the first 6 weeks of life.

The natural history for patients with isolated VSDs is highly variable. Most VSDs are restrictive and tend to close spontaneously during the first year of life. Large VSDs are nonrestrictive, resulting in right ventricular and pulmonary pressures that are systemic or nearly systemic, and high PBF with Q_p/Q_s ratios greater than 2.5 to 3. Moderate VSDs are restrictive, with pulmonary pressures that are one-half systemic (or less) and Q_p/Q_s ratios of 1.5 to 2.5. Small VSDs are highly restrictive; right ventricular pressures remain normal, and the Q_p/Q_s is less than 1.5. Patients with large VSDs tend to develop symptoms of CHF by 2 months of age. Patients with smaller VSDs may remain asymptomatic. In patients with outlet VSDs, prolapse of the aortic valve may occur, producing aortic insufficiency.¹⁹ Untreated, excessive PBF leads to pulmonary vascular obstructive disease by the second year of life. The histologic changes associated with pulmonary vascular obstructive disease have been classified by Heath and Edwards based on severity.²⁰ Grade 1 consists of medial hypertrophy; grade 2 reflects intimal proliferation; grade 3 is characterized by intimal fibrosis and vascular occlusion; and grades 4 through 6 describe progressive vessel dilatation, angiomatoid malformation, and necrotizing arteritis. Grades 1 and 2 are considered reversible, whereas the latter stages are irreversible.

Signs of heart failure in infants with large VSDs include tachypnea, hepatomegaly, poor feeding, and failure to thrive. On physical examination, there is a holosystolic murmur at the left sternal border. Usually, the murmur is louder with smaller defects. The precordium is active. The pulmonary component of the second heart sound is accentuated in the presence of pulmonary hypertension. Chest radiography shows increased pulmonary vascular markings and cardiomegaly. ECG is significant for right ventricular hypertrophy. Patients with small VSDs have little shunting and are usually asymptomatic, having only a pansystolic murmur. Patients with moderate VSDs manifest symptoms and signs that are proportional to the degree of shunting. In patients who have developed significant pulmonary vascular obstructive disease, the volume of left-to-right shunting is decreased, and the murmur may disappear. Eisenmenger physiology results when the shunt flow reverses to right to left, creating cyanosis.

The diagnosis of VSD is confirmed by echocardiography, which accurately defines the anatomy and excludes the presence of associated defects. Cardiac catheterization is used selectively in older children and adults in whom elevated PVR is suspected. PVR is calculated by the following formula:

$$PVR = (PA_{\text{mean}} - LA)/Q_p$$

where PA_{mean} is the mean pulmonary artery pressure and LA is the left atrial pressure. The units of resistance by this formulation (using pressures in millimeters of mercury and pulmonary flow in liters per minute) are Woods units (which can be expressed in dynes/s per cm^5 by multiplying by 80). In the pediatric population, vascular resistance is frequently calculated using the cardiac output indexed to the body surface area (in square meters) with the resulting indexed resistance units of Woods units/ m^2 . PVR may be fixed or reactive, and, at the time of cardiac catheterization, response to nitric oxide or 100% fraction of inspired oxygen (FiO_2) may be assessed.

The management of a patient with a VSD depends on the size of the defect, the type of defect, the shunt volume, and the PVR. In general, patients with large defects who have intractable CHF or failure to thrive should undergo early surgical repair. If the congestive symptoms can be moderated by medical therapy, then surgery may be deferred until 6 months of age. Patients with moderate VSDs may be safely followed. If closure has not occurred by school age, then surgical closure is indicated. Small VSDs with a Q_p/Q_s ratio of less than 1.5 do not require closure unless there is evidence of left-sided chamber enlargement. There is a small long-term risk of endocarditis for these patients, but this can be minimized with the appropriate use of prophylactic antibiotics.²¹ Patients with outlet VSDs have a risk of developing aortic insufficiency due to leaflet prolapse, and, therefore, all of these patients should undergo surgical closure.²² Older children and adults must undergo catheterization to assess the pulmonary circulation. When there is a fixed PVR greater than 8 to 10 Woods units/ m^2 , then surgery is contraindicated.

Surgical closure is performed through a median sternotomy. Cardiopulmonary bypass is employed with bicaval cannulation, and the patient is typically cooled to 32°C. After aortic cross-clamping, cold cardioplegia is delivered through the aortic root to arrest the heart. Exposure of the ventricular septum is most often achieved by making a right atriotomy and retracting the leaflets of the tricuspid valve. This provides access to perimembranous, inlet, and most trabecular VSDs. Outlet VSDs are frequently best exposed via a pulmonary arteriotomy because the defect lies just beneath the valve. Trabecular

VSDs located near the ventricular apex can be very difficult to expose, and an apical ventriculotomy may be necessary. Once the defect is exposed, it is closed using a polytetrafluoroethylene patch and a running polypropylene suture, although other centers may prefer other patch material or interrupted suture technique. It is important to understand the anatomy of the conduction tissue when closing VSDs. The AV node is an atrial structure that lies at the apex of an anatomic triangle (known as the triangle of Koch) formed by the coronary sinus, the tendon of Todaro (a prominent band leading from the inferior vena cava and inserting in the atrial septum), and the septal attachment of the tricuspid valve. The node then gives rise to the bundle of His, which penetrates the AV junction beneath the membranous septum. The bundle of His then bifurcates into right and left bundle branches, which pass along either side of the muscular ventricular septum. In the presence of a perimembranous VSD, the bundle of His passes along the posterior and inferior rim of the defect, generally on the left ventricular side. In this critical area, sutures must be placed superficially on the right ventricular side a few millimeters from the edge of the defect. The bundle of His also tends to run along the posterior and inferior margin of inlet VSDs. The conduction tissue is usually remote from outlet and trabecular VSDs.

PA banding is a palliative maneuver that is used to protect the pulmonary circulation from excessive blood flow. PA banding is currently performed only in patients who are felt to be poor candidates for VSD closure, either due to associated illness or due to anatomic complexity, such as multiple trabecular VSDs (“Swiss cheese” septum). Banding is performed without the need for cardiopulmonary bypass. A band is placed around the main PA and tightened to achieve a distal PA pressure of about one-half systemic. The band is secured to the adventitia of the PA to prevent its migration. Distal migration may result in narrowing and poor growth of one or both branch pulmonary arteries, whereas proximal migration can cause deformity of the pulmonary valve. Later, when the patient is a candidate for VSD closure, the band must be removed. Repair of the main PA at the band site is also usually necessary and can typically be accomplished by scar resection and primary closure or patch repair.

Surgical closure of a VSD is associated with a mortality less than 1%.²³ Potential complications include injury to the conduction tissue and injury to the tricuspid or aortic valves. Transient heart block may result from tissue swelling or injury from retraction, but permanent heart block occurs in less than 1% of cases. When heart block develops after surgery, patients are usually observed for a period of 7 to 10 days prior to permanent pacemaker implantation. Closure of perimembranous and inlet VSDs may result in distortion of the tricuspid valve, which may cause significant regurgitation. Aortic valve injury may occur as a result of inaccurate suturing, especially in perimembranous and outlet defects. A residual VSD is seen in about 5% of cases, and reoperation is indicated when significant shunting persists (Q_p/Q_s ratio > 1.5). The Q_p/Q_s ratio can be calculated by measuring oxygen saturations and using the following formula derived from the Fick equation:

$$Q_p/Q_s = (Ao - SVC)/(PV - PA)$$

where Ao is the aortic (or systemic) saturation, SVC is the saturation in the superior vena cava, PV is the saturation in the pulmonary veins (which is usually estimated to be 95% to 100%), and PA is the saturation in the pulmonary arteries. Intraoperative echocardiography is used routinely to identify residual defects, which can then be repaired before the patient leaves the operating room.

Recently, transcatheter devices have been developed to allow closure of some VSDs in the cardiac catheterization laboratory or by periventricular deployment without the use of cardiopulmonary bypass.^{24,25} Device closure is optimal for large muscular defects with sufficient rims for securing the device. These defects are often difficult to visualize and close surgically. Periventricular closure allows the use of VSD device closure in smaller infants with symptomatic muscular VSDs with excellent results without the challenges of transvenous access in this population.²⁵ The use of devices for perimembranous VSDs remains limited by the risk of damage to the conduction system or impingement on the function of the tricuspid or aortic valves. A recent series demonstrated a 22% rate of complete heart block, which is prohibitively high in comparison to the surgical rate of complete heart block of less than 1%.²⁶

ATRIOVENTRICULAR SEPTAL DEFECT

4 Defects in the embryologic development of the endocardial cushions may result in a variety of morphologic abnormalities in the AV valves and the atrial and ventricular septa. These anomalies range from ostium primum ASD to complete AVSD (or AV canal defect), with a spectrum of intermediate forms. PDA and TOF are occasionally seen in association with these defects. A high percentage of

patients with abnormalities of the AV structures have trisomy 21 (Down syndrome). All infants with trisomy 21 should have an echocardiogram to rule out congenital heart disease given a prevalence of 50%.

Complete AVSD is an anomaly characterized by a common AV orifice, rather than separate mitral and tricuspid orifices, and a deficiency of endocardial cushion tissue, which results in a primum ASD and an inlet type of VSD. Complete AVSDs were subclassified by Rastelli et al.²⁷ into three types according to the morphology of the anterior leaflet of the common AV valve (Table 81-1). Incomplete AVSDs are variants in which there is partial fusion of the AV valves, resulting in separate right and left AV valve orifices. The ostium primum ASD is a type of incomplete AVSD in which the VSD component is absent.

Table 81-1 Rastelli Classification of Atrioseptal Ventricular Defects

Type	Description
A	The anterior bridging leaflet is divided and attached to the septum by multiple chordae.
B	The anterior bridging leaflet is attached to a papillary muscle in the right ventricle.
C	The anterior bridging leaflet is free-floating, with no attachments except to the valve annulus.

When both left and right AV valves equally share the common AV valve orifice, the AVSD is termed *balanced*. Occasionally, the orifice may favor the right AV valve (right dominance) or the left AV valve (left dominance). In marked right dominance, the left AV valve and LV are hypoplastic, and frequently coexist with other left-sided abnormalities, including aortic stenosis (AS), hypoplasia of the aorta, and coarctation. Conversely, marked left dominance results in a deficient right AV valve with associated hypoplasia of the right ventricle, PS or atresia, and TOF. Patients with severe imbalance require staged single-ventricle reconstruction.

The conduction tissue is displaced in an ASVD and is at risk during surgical repair. The AV node is located posteriorly and inferiorly of its normal position toward the coronary sinus in what has been termed the *nodal triangle*. This triangle is bounded by the coronary sinus, the posterior attachment of the inferior bridging leaflet, and the rim of the ASD. The bundle of His courses anteriorly and superiorly to run along the leftward aspect of the crest of the VSD, giving off the left bundle branch and continuing as the right bundle branch.

A number of other cardiac anomalies are associated with AVSDs including a PDA (10%) and TOF (10%).²⁸ Important abnormalities of the left AV valve include single papillary muscle (parachute mitral valve) (2% to 6%) and double orifice mitral valve (8% to 14%).²⁹ A persistent left superior vena cava with or without an unroofed coronary sinus is encountered in 3% of patients with an AVSD. Double-outlet right ventricle (DORV) (2%) significantly complicates or may even preclude complete surgical correction.²⁸ Left ventricular outflow tract obstruction from subaortic stenosis or redundant AV valve tissue occurs in 4% to 7%.^{30,31}

Patients with an incomplete AVSD generally present in a similar fashion as a patient with a large secundum ASD. Patients with a complete AVSD with both atrial and ventricular level shunting generally present early in infancy with signs and symptoms of CHF. In addition, moderate or severe left AV valve regurgitation occurs in approximately 10% of patients with an AVSD, worsening the clinical picture. On physical examination, the precordium is hyperactive, often with a prominent thrill. Auscultatory findings include a systolic murmur along the left sternal border, a high-pitched murmur at the apex from left AV valve regurgitation, and a middiastolic flow murmur across the common AV valve. In the presence of elevated PVR, there may be a split first heart sound. Significant cardiomegaly and pulmonary overcirculation are found on the chest radiograph. ECG reveals biventricular hypertrophy, atrial enlargement, prolonged PR interval, leftward axis, and counterclockwise frontal plane loop. Doppler/echocardiography is diagnostic, defining the atrial and ventricular level shunting, valvular anatomy, and any associated anomalies. Cardiac catheterization should be performed for patients older than 1 year of age, for patients with signs or symptoms of increased PVR, or in some cases to further evaluate other associated major cardiac anomalies. If the PVR is high, it is important to remeasure it while the child is breathing 100% oxygen with and without nitric oxide. If the pulmonary resistance falls, it implies that much of the elevated resistance is dynamic and can be managed in the perioperative period by ventilatory manipulation, supplemental oxygen, and nitric oxide. More recently, sildenafil has been shown to decrease elevation in PVR in children with CHF.³² Markedly elevated pulmonary

resistance (>10 Woods units/m²) that does not respond to oxygen administration is generally considered a contraindication to repair.

Operative treatment is almost always necessary as soon as symptoms are observed to prevent further clinical deterioration. Even in the absence of symptoms, operation is best performed before 6 months of age. PA banding, which permits delaying the repair until the child is larger, is no longer used today except in select complex or single-ventricle cases, extremely low birth weight or prematurity, and very poor clinical condition. This approach exposes the child to the risks of two operations, and the overall mortality exceeds that of primary repair in infancy.

Correcting AVSDs requires patch closure of both septal defects, with any necessary valve reconstruction. Separate atrial and ventricular patches or a single patch for both chambers can be used.³³ During closure of the ventricular defect, the surgeon must carefully avoid injury to the conduction system, which passes along the posterior and inferior rim of the ventricular septum.

The short- and long-term success of the operation is highly dependent on the status of the PVR and the surgeon's ability to maintain competence of the mitral valve. Although earlier reports recommend that the cleft in the left AV valve should not be closed and the valve treated as a trileaflet structure, most surgeons now believe that closure of the cleft is an important mechanism in preventing postoperative left AV valve regurgitation. Significant AV valve regurgitation at the conclusion of surgery, severe dysplasia of the left AV valve, and failure to close the cleft of the left AV valve have been identified as important risk factors for reoperation.³⁴ Significant postoperative left AV valve regurgitation is also a risk factor for operative and long-term mortality.^{30,34} The cleft should not be completely closed in the presence of a single papillary muscle to avoid causing left AV valve stenosis. In the case of a double-orifice valve, the bridging tissue should not be divided to create a single opening in the valve.

Operative mortality is related largely to associated cardiac anomalies and left AV valve regurgitation. Mortality for repair of uncomplicated incomplete AVSDs ranges from 0% to 0.6%, and the addition of left AV valve regurgitation increases mortality to 4% to 6%.^{30,35} For complete AVSDs, the mortality without left AV valve regurgitation is approximately 5%, compared with 13% when significant degrees of regurgitation are present.³⁰

The majority of reoperations after repair of AVSD are due to left AV valve regurgitation or subaortic stenosis with reoperation rates at 5 years of 11% and 10%, respectively.³⁶ Significant postoperative AV valve regurgitation occurs in 10% to 15% of patients, necessitating reoperation for valve repair or replacement in 7% to 12%.^{34,37,38} Long-term survival is excellent with rates at 1, 3, and 5 years of 98%, 95%, and 95%, respectively.³⁶

TETRALOGY OF FALLOT

5 TOF is the most common cyanotic congenital heart defect. It occurs in 0.6 per 1,000 live births and has a prevalence of about 5% among all patients with congenital heart disease.⁷ The pathologic anatomy is frequently described as having four components: VSD, overriding aorta, PS, and right ventricular hypertrophy (Fig. 81-3). Embryologically, the anatomy of TOF is thought to result from a single defect: anterior malalignment of the infundibular septum.³⁹ The infundibular septum normally separates the primitive outflow tracts and fuses with the ventricular septum. Anterior malalignment of the infundibular septum creates a VSD due to failure of fusion with the ventricular septum and also displaces the aorta over the VSD and right ventricle. Infundibular malalignment also crowds the right ventricular outflow tract, causing PS and, secondarily, right ventricular hypertrophy. Prominent muscle bands also extend from the septal insertion of the infundibular septum to the right ventricular free wall and contribute to the obstruction of the right ventricular outflow tract. The pulmonary valve is usually stenotic and is bicuspid in 58% of cases.⁴⁰ Pulmonary atresia occurs in about 7% of cases of TOF. The branch pulmonary arteries in TOF may exhibit mild diffuse hypoplasia or discrete stenosis (most frequently of the left PA at the site of ductal insertion). Coronary artery anomalies are frequently present. The origin of the left anterior descending from the right coronary artery, which occurs in 5% of cases, is clinically important because the vessel crosses the right ventricular infundibulum and is vulnerable to injury at the time of surgery. A right aortic arch is present in 25% of patients with TOF. Associated defects include ASD, complete AVSD, PDA, or multiple VSDs.

Figure 81-3. The four anatomic features of tetralogy of Fallot. The primary morphologic abnormality, anterior and superior displacement of the infundibular septum, results in a malalignment ventricular septal defect, overriding of the aortic valve, and obstruction of the right ventricular outflow. Right ventricular hypertrophy is a secondary occurrence.

Patients with TOF develop cyanosis due to right-to-left shunting across the VSD. The degree of cyanosis depends on the severity of obstruction of the right ventricular outflow tract. Frequently, cyanosis is mild at birth and may remain undetected for weeks or months. Neonates with severe infundibular obstruction or pulmonary atresia will develop symptoms shortly after birth and will require a prostaglandin infusion to maintain ductal patency to ensure adequate PBF. In other patients, the right ventricular outflow tract obstruction is minor, and the predominant physiology is that of a large VSD with left-to-right shunting and CHF.

The occurrence of intermittent cyanotic spells is a well-known feature of TOF. The etiology of spelling is still controversial but is clearly related to a transient imbalance between pulmonary and systemic blood flow. A spell may be triggered by hypovolemia or peripheral vasodilation (e.g., after a bath or vigorous physical exertion). Spells may occur in neonates, but are most frequently reported in infants between the ages of 3 and 18 months. Most spells resolve spontaneously within a few minutes, but some spells may be fatal. Older children have been observed to spontaneously squat to terminate spells. The squatting position is thought to increase systemic vascular resistance, which thereby favors PBF.

Cyanosis is the most frequent physical finding in tetralogy. Auscultation reveals a normal first heart sound and a single second heart sound. A systolic ejection murmur is present at the left upper sternal border. Older children may develop clubbing of the fingers and toes. Chest radiography typically demonstrates a boot-shaped heart due to elevation of the cardiac apex from right ventricular hypertrophy. Pulmonary vascular markings are usually reduced. A right aortic arch may be present. An ECG shows right ventricular hypertrophy. Echocardiography is definitive, and catheterization is not necessary in most cases.

The medical management of TOF is directed toward the treatment and prevention of cyanotic spells. The immediate treatment of the spelling patient includes administration of oxygen, narcotics for sedation, and correction of acidosis. Transfusion is indicated for anemic infants. α -Agonists are useful for increasing systemic vascular resistance (which favors PBF). Some centers have used beta blockers as a form of long-term therapy to suppress the incidence of spells.

All patients with TOF should undergo surgical repair. Asymptomatic patients should be repaired electively between 4 and 6 months of age. Early repair is indicated for neonates with severe cyanosis and for infants who have had a documented spell or worsening cyanosis.

Classically, the repair of TOF was accomplished in two stages. During the first stage, PBF was augmented by creating a connection (or shunt) between a systemic artery and the PA. At the second stage, the shunt was taken down, and a complete repair was performed. The first shunt procedure was the Blalock–Taussig shunt, in which the subclavian artery was mobilized and divided distally, and an end-to-side anastomosis was created between the inferiorly deflected subclavian and the ipsilateral PA. Other shunt operations were subsequently developed and involved connections between the ascending aorta and right PA (Waterston shunt) or between the descending aorta and left PA (Potts shunt). The modified Blalock–Taussig shunt is the most common type of shunt used today and consists of an interposition graft (polytetrafluoroethylene) between the innominate or subclavian artery and the ipsilateral PA. Creation of a shunt may be accomplished with or without the use of cardiopulmonary bypass.

Currently, one-stage repair of TOF is preferred by most centers. Initial palliation with a shunt is still indicated for some patients who are at high risk for early complete repair, such as those with multiple congenital anomalies, severe concurrent illness, intracranial hemorrhage, or an anomalous coronary artery crossing a hypoplastic infundibulum. In the absence of these risk factors, complete repair in the symptomatic neonate can be performed with lower mortality and reoperation rate compared to staged palliation.^{41,42}

Complete repair of TOF is performed using a median sternotomy and cardiopulmonary bypass with bicaval venous cannulation. By a transatrial approach, the right ventricular outflow tract can be examined through the tricuspid valve. Muscle bundles obstructing the right ventricular outflow tract are divided or rarely resected. The VSD is closed with a patch. Pulmonary valvotomy is performed, when indicated, via a vertical incision in the main PA. When the pulmonary valve annulus or infundibulum is severely hypoplastic, a transannular outflow tract patch may be necessary to relieve the obstruction. When an anomalous coronary artery crosses the infundibulum, a transannular incision may be contraindicated. In these cases, and in patients with pulmonary atresia, placement of a conduit (cryopreserved homograft, valved xenograft, or bioprosthetic heterograft) between the right ventricle (via a separate ventriculotomy) and main PA will be necessary. Patients who have a transannular patch develop pulmonary insufficiency as a consequence. This is surprisingly well tolerated in most infants and children, as long as the tricuspid valve is competent. As these patients grow older, some will develop right ventricular failure due to chronic pulmonary insufficiency, and pulmonary valve implantation may be necessary, often in the second or third decade of life.^{43,44}

The early mortality following repair of TOF is between 1% and 5%.^{40,45} The results are worse for patients with TOF and pulmonary atresia. Long-term complications include recurrent obstruction of the right ventricular outflow tract and development of right ventricular dysfunction due to chronic pulmonary insufficiency. Actuarial survival at 20 years is 86% with excellent functional status.⁴⁶

DOUBLE-OUTLET RIGHT VENTRICLE

Double-outlet ventricle includes a variety of malformations in which, by 50% or more, both great arteries arise from one ventricle. Although double-outlet LVs occur, a far more common anomaly is the DORV. A VSD is usually present in DORV, in addition to other defects, including discordant ventriculoarterial connections, valvar or subvalvar stenosis of the PA and aortic outflow, and single ventricle.

The physiologic consequences of DORV vary depending on the associated defects. The three most critical factors determining the net effects on the circulation are the size of the VSD, the presence or absence of PS, and the presence and degree of left-sided obstruction. As a result, DORV may clinically resemble an isolated VSD, TOF, or transposition of the great arteries (TGA).

The size and location of the VSD are important considerations in planning operative management. The VSD may be primarily directed toward the aorta, toward the PA, equally toward both arteries (doubly committed), or remote from both great vessels (noncommitted). The location of the VSD affects the direction of flow of oxygenated blood and thus affects the degree of cyanosis. VSDs in DORV seldom close spontaneously. This is fortunate, as closure would result in severe hemodynamic decompensation or death.

If the VSD is large, nonrestrictive, and committed to the aorta, it can be closed with a tunnel-like patch that directs left ventricular flow into the aorta. A restrictive VSD must be enlarged to avoid creating subaortic stenosis. For patients with DORV and PS, repair requires right ventricular outflow tract reconstruction with a patch or a valved allograft conduit, in addition to patch closure of the VSD.

DORV with transposition-type physiology (malposed great vessels with the VSD committed to the PA), also known as a Taussig–Bing anomaly, may be treated by a variety of methods, depending on the specific anatomic details. The preferred approach would be to perform an arterial switch operation, thus making the VSD committed to the aorta, and baffling the left ventricular outflow from the VSD to this neo-aorta. Another preferred approach, which depends on a favorable orientation of the two great vessels and VSD, would be an intraventricular tunnel from the VSD to the aorta. A third approach utilizes the Damus–Kaye–Stanzel operation (DKS). During the DKS, the proximal PA is anastomosed end to side into the aorta. The VSD is baffled to both semilunar valves, which both connect to the aorta. An extracardiac conduit is then placed to reconstruct right ventricle-to-PA continuity. This approach may also be useful when the VSD is doubly committed or noncommitted, so that making a direct connection to either single great vessel is problematic.

The current results for correction of DORV with subaortic VSD are excellent, with a 15-year survival, including hospital mortality, of 96%.^{47,48} Mortality for the more complex repairs tends to be slightly higher. Hospital mortality for an arterial switch operation with VSD closure for DORV ranges from 3.7% to 14.3%.^{49,50}

TRANSPOSITION OF THE GREAT ARTERIES

6 TGA is a congenital cardiac anomaly in which the aorta arises from the right ventricle and the PA originates from the LV (ventriculoarterial discordance; Fig. 81-4). Looping refers to the right or left looping of the primitive heart tube during fetal development, which determines whether the atria and ventricles are concordant (right atrium attaches to right ventricle and left atrium attaches to LV) or discordant. Levo-TGA (l-TGA) is associated with AV discordance (right atrium attaches to LV and left atrium attaches to right ventricle), and is also termed *congenitally corrected TGA*. l-TGA is a rare variant of TGA and is beyond the scope of this chapter, which will focus on dextro-TGA (d-TGA). The defect can be subdivided into d-TGA with intact ventricular septum (IVS) (55% to 60%) and d-TGA with VSD (40% to 45%), one third of which are hemodynamically insignificant. Pulmonic stenosis (PS), causing significant left ventricular outflow tract obstruction, occurs rarely with an IVS and in approximately 10% of d-TGA/VSD.⁵¹

d-TGA is a relatively common cardiac anomaly and is the most common form of congenital heart disease presenting as cyanosis in the first week of life. The malformation accounts for approximately 10% of all congenital cardiovascular malformations in infants.⁵² The degree of cyanosis depends on the amount of mixing between the pulmonary and systemic circulations. In d-TGA, oxygenated pulmonary venous blood is returned to the lungs and desaturated systemic blood is returned to the body. Because the two circulations exist in parallel, some mixing between them must occur to allow oxygenated blood to reach the systemic circulation and the desaturated blood to reach the lungs. Mixing may occur at a number of levels, most commonly at the atrial level through an ASD or a PFO. Generally, two levels of mixing are necessary to maintain adequate systemic oxygen delivery with a VSD or PDA serving as an additional site for cardiac mixing. In d-TGA, there can be no fixed shunt in one direction without an equal amount of blood passing in the other direction; otherwise, one circulation would eventually empty into the other. Therefore, the amount of desaturated blood reaching the lungs (effective PBF) must equal the amount of saturated blood reaching the aorta (effective systemic blood flow). Clinical characteristics are dependent on the degree of mixing and the amount of PBF. These factors relate to the specific anatomic subtype of d-TGA. Neonates with d-TGA with IVS (or small VSD) have mixing limited to the atrial level and PDA. The ASD may be restrictive and the PDA generally will close over the first days to week of life. As the degree of mixing decreases, the patient becomes increasingly cyanotic and will eventually suffer cardiovascular collapse. Fortunately, the majority of these neonates will manifest cyanosis early in life, which is recognized by a nurse or physician within the first hour in 56% and in the first day in 92%.⁵³ In d-TGA with a large VSD, there is additional opportunity for mixing and increased PBF. The neonate with d-TGA/VSD may only manifest mild cyanosis, which may be initially overlooked. However, generally within 2 to 6 weeks signs and symptoms of CHF will emerge. Tachypnea and tachycardia become prominent, whereas cyanosis may remain mild. Auscultatory findings are consistent with CHF with increased PBF, including a pansystolic murmur, third heart sound, middiastolic rumble, gallop, and narrowly split second heart sound with increased pulmonary component. Neonates with d-TGA and significant PS present with severe cyanosis at birth. Lesser degrees of PS will result in varying levels of cyanosis. The ECG is normal at birth, demonstrating the typical pattern of right ventricular dominance. Although the classic chest radiographic appearance of an egg-shaped heart with a narrow superior mediastinum may be seen, this finding is often obscured by an enlarged thymic shadow. The abnormal ventriculoarterial connection is clearly seen on echocardiography, which demonstrates that the posterior great vessel arising from the LV is a PA that bifurcates soon after its origin. The anterior great vessel is the aorta and arises from the right ventricle. Associated lesions, including VSD, left ventricular outflow tract obstruction, and coarctation, may also be diagnosed. Although used less frequently, cardiac catheterization may be helpful to confirm the basic anatomy, discern associated lesions, define the coronary anatomy, and improve cardiac mixing by means of balloon atrial septostomy.

Figure 81-4. Anatomy of the most common type of transposition of the great arteries. The location of the ascending aorta is usually anterior to and to the right of the pulmonary artery.

The infant with d-TGA and severe cyanosis requires prompt diagnosis and treatment to improve mixing and increase the arterial oxygen saturation. The first intervention to improve mixing in a cyanotic newborn suspected of having d-TGA is to ensure ductal patency by beginning an infusion of prostaglandin E₁ (PGE₁). In the presence of a restrictive ASD, a balloon atrial septostomy, a technique developed by William Rashkind⁵⁴ in 1966, is performed. The procedure involves inserting a balloon-tipped catheter across the foramen ovale into the left atrium. Inflation and forcible withdrawal of the catheter tears the septum primum and enlarges the ASD. Mixing generally increases immediately, with a substantial increase in arterial oxygen saturation.

Without intervention, d-TGA is universally fatal. Untreated, 30% of neonates will die in the first week of life, 50% by the first month, 70% within 6 months, and 90% by 1 year.⁵⁵ The definitive surgical treatment of patients with d-TGA has changed dramatically in the past decade with the advent of the arterial switch operation. Before this procedure, repair of d-TGA was generally delayed until patients were at least 6 months of age. Historically, palliative procedures were often necessary to improve the systemic saturation or protect the pulmonary vascular bed before definitive repair. If balloon atrial septostomy failed to enlarge the ASD adequately, a Blalock–Hanlon septectomy was performed. Rarely used today, this operation is a method of surgically enlarging the ASD without cardiopulmonary bypass. In patients with large VSDs, significant CHF and pulmonary hypertension are present early in life. Historically, the main PA was banded to reduce distal PA pressure and prevent the development of pulmonary vascular occlusive disease. Changes of pulmonary vascular disease may develop in about 25% of patients with hemodynamically large VSDs by 3 months of age; therefore, early reduction of PA pressure was essential. In those cases of transposition with severe left ventricular outflow tract obstruction, total pulmonary flow is reduced and systemic-to-PA shunting was undertaken until definitive repair could be accomplished.

Historically, definitive repair was achieved by redirecting venous inflow at the atrial level. First successfully performed by Senning⁵⁶ in 1959, the operation was further modified by Mustard⁵⁷ in 1964 (Fig. 81-5). In both techniques, the atrial septum is repositioned such that superior and inferior vena caval blood is rerouted to the mitral valve and then to the LV and PA. Pulmonary venous blood is redirected to the tricuspid valve and right ventricle. The right ventricle then ejects the oxygenated blood to the systemic circulation. The Mustard operation uses a large patch of pericardium or prosthetic material to create the intra-atrial baffle. In the Senning procedure, the patient's atrial tissue is used, and little or no foreign material is necessary. Although physiologic repair at the atrial level is associated with a low operative mortality rate (<5%), even in infants, a number of late problems have occurred. Obstruction to vena caval inflow, particularly at the junction of the superior vena cava and the right atrium, still occurs in about 5% of patients and may be more common when the procedure is performed in an infant. Additionally, pulmonary venous obstruction may develop and is often difficult to repair. Perhaps because of the complex atrial suture lines, atrial dysrhythmias are common and occur in more than half of patients observed on a long-term basis. In addition, pacemakers may be necessary for troubling bradyarrhythmias in as many as 10% of these patients.

Figure 81-5. The Mustard operation for transposition of the great arteries. In this procedure, the atrial septum is excised and replaced with a pericardial baffle, so that pulmonary venous blood is redirected over the baffle to the tricuspid valve. Superior and inferior vena caval blood then drains to the mitral valve.

The most serious long-term complication of repair by either the Senning or Mustard technique has been right ventricular dysfunction. Right ventricular failure with an enlarged, poorly contractile chamber and secondary tricuspid regurgitation has been found in a significant number of these patients in long-term follow-up studies. The true incidence of significant right ventricular failure in these cases remains difficult to define and is clearly influenced by an earlier era of operation with different methods of myocardial protection and surgical technique. The fact that many of these infants underwent definitive repair after many months of significant cyanosis may also have influenced right ventricular function.

The long-term complications of atrial repair prompted a reexamination of direct arterial repair for transposing the great arteries. The “arterial switch” operation, first successfully performed by Jatene in 1975, has become the optimal surgical procedure for infants with this condition.⁵⁸ Current techniques have reduced the operative mortality to levels comparable with those of atrial repair. Additionally, because the operation is performed early in life, this approach has virtually eliminated the interim morbidity and mortality associated with postponement of surgery until at least 6 months of age. The operative technique involves transection of both great vessels and direct reanastomosis to reestablish ventriculoarterial concordance (Fig. 81-6). Additionally, the coronary arteries are removed from the anterior aorta and relocated to the posterior great vessel (neo-aorta). The extensive experience gained with this procedure has confirmed that any variant of coronary artery anatomy can be successfully repaired. Certain coronary anatomy variants were previously felt to be associated with higher risk; however, this concern has been neutralized in recent series.^{59,60} Many patients with d-TGA have an IVS, and left ventricular pressure falls early in life as PVR decreases. In this situation, it is essential that the arterial repair be performed within the first 1 to 2 weeks of life, while the LV is still able to meet systemic workloads. In patients presenting later, the LV can be retrained with a preliminary PA banding and an aorticopulmonary shunt, if necessary, followed by the definitive arterial repair. Although patients with large VSDs do not require early repair because they maintain systemic left ventricular pressures, experience has indicated that, even in this subgroup, the operation is best performed within the first month of life, before secondary complications such as pulmonary hypertension, CHF, or infection develop.

Patients with fixed left ventricular outflow tract obstruction are not candidates for the arterial repair because correction would result in systemic ventricular outflow tract obstruction. Most of these patients also have large VSDs. Palliation early in life with systemic-to-PA shunting is an option, with definitive repair postponed until somatic growth results in cyanosis as the shunt is outgrown. At that time, the Rastelli procedure is performed, in which left ventricular blood is redirected through the VSD and to the anterior aorta by placement of an intraventricular patch (Fig. 81-7). The PA is ligated, and right ventricle-to-distal PA continuity is reestablished with a valved conduit. An increasing number of experienced centers currently recommend early complete repair in the neonatal period using a Rastelli procedure. Early repair eliminates the interim morbidity and mortality associated with a systemic-to-PA

shunt and chronic cyanosis.

Current hospital survival for the arterial switch operation ranges from approximately 90% to 98%.^{51,59-62} In earlier eras, d-TGA/IVS had a lower operative mortality than d-TGA/VSD; however, recent studies have neutralized this difference.^{59,60} Complex d-TGA including d-TGA/VSD/PS and d-TGA/VSD with aortic arch hypoplasia are independent predictors of increased operative mortality.^{63,64} Coronary artery anatomy does not affect mortality.⁵⁹ Long-term survival at 5 to 10 years and 15 years ranges from 87% to 93% and 86% to 88%, respectively.⁶⁰⁻⁶² The most common cause for reintervention is supravulvar PS, occurring in 3.9% to 16%.^{61,62} Late follow-up of arterial switch operation patients has led to increased concern regarding coronary artery patency and neo-aortic root dilation.⁶⁵

LeCompte maneuver; posterior translocation of the aorta. C: Mobilization of the coronary arteries. D: Placement of pantaloons-shaped pericardial patch. E: Proper alignment of the coronary arteries on the neoaorta. F: Completed repair.

Figure 81-7. The Rastelli procedure for transposition of the great arteries with ventricular septal defect and pulmonary stenosis. A prosthetic patch placed within the right ventricle directs left ventricular blood through the defect to the aorta. The main pulmonary artery is ligated, and right ventricular blood then passes through a conduit to the distal pulmonary arteries.

TRUNCUS ARTERIOSUS

Truncus arteriosus is a rare anomaly that accounts for 0.4% to 4% of all cases of congenital heart disease.^{66–68} A single arterial vessel arises from the heart, overriding the ventricular septum and giving rise to the systemic, coronary, and pulmonary circulations. Two classification schemes have been proposed: one by Collett and Edwards⁶⁹ in 1949 and the other by Van Praagh and Van Praagh⁷⁰ in 1965 (Fig. 81-8). The Collett and Edwards classification focused on the origin of the pulmonary arteries from the common arterial trunk (Table 81-2). The system offered by Van Praagh and Van Praagh, a somewhat more surgically oriented scheme, is based on the presence or absence of a VSD, the degree of formation of the aortopulmonary septum, and the status of the aortic arch (Table 81-3).

Persistent truncus arteriosus is the result of failed development of the aortopulmonary septum and subpulmonary infundibulum (conal septum). Normal septation leads to the development of both pulmonary and systemic outflow tracts, division of the semilunar valves, and formation of the aorta and pulmonary arteries. Failure of septation results in a VSD (absence of the infundibular septum), a single semilunar valve, and a single arterial trunk. Most cases are associated with a VSD reminiscent of the VSD associated with TOF. However, in this anomaly, the superior margin of the defect is formed by the truncal valve. The truncal valve leaflets are generally dysmorphic, and their motion may be restricted. Leaflet number is highly variable, with about 65% tricuspid, 22% quadricuspid, 9% bicuspid, and rarely unicuspid or pentacuspid.⁷¹ As a result of these abnormally developed valve leaflets, a moderate or greater degree of truncal insufficiency is present in 20% to 26% of patients.^{72,73} Mild stenosis is common; however, significant stenosis is present in only 4% to 7%.^{72,73} Significant obstruction is predicted by gradients of more than 30 mm Hg in the presence of a normal cardiac output.⁷⁴ The PAs are usually of normal size and most often arise from the left posterolateral aspect of the truncal artery, often in close proximity to the truncal valve and ostium of the left coronary artery.

Other cardiac anomalies are common, with a PFO usually present. A true ASD is found in 9% to 20%, a persistent left superior vena cava in 4% to 9%, and mild tricuspid valve stenosis in 6%.^{28,75} An interrupted aortic arch, most commonly type B, is present in association with truncus arteriosus (Van Praagh type A4/B4) in approximately 10% to 20%.^{76,77} The arch is rightward, generally with mirror-image branching, in 21% to 36%.^{75,77} Aberrant origins of the brachiocephalic vessels are reported, most commonly an aberrant right subclavian artery in 4% to 10%.^{75,78} Coronary ostial abnormalities are of particular surgical significance and occur in 37% to 49% of cases.⁷⁹ The left coronary artery is frequently noted to have a high origin, not uncommonly near the takeoff of the pulmonary arteries. Rarely, the left coronary can originate from the main pulmonary trunk or a branch PA.⁷⁸ Extracardiac anomalies are reported in approximately 28% of patients with truncus arteriosus.⁷² Described abnormalities include skeletal, genitourinary, and gastrointestinal deformities. As mentioned earlier, monoallelic microdeletion of chromosome 22q11 is common, with DiGeorge syndrome diagnosed in at least 11%.⁷²

Figure 81-8. Truncus arteriosus: classification schemes as described by Collett and Edwards⁶⁹ and by Van Praagh and Van Praagh.⁷⁰ (Adapted from Hernanz-Schulman M, Fellows KE. Persistent truncus arteriosus: pathologic, diagnostic, and therapeutic considerations. *Semin Roentgenol* 1985;20:121.)

Table 81-2 Collett and Edwards Classification of Truncus Arteriosus

Type	Description
I	Common arterial trunk gives rise to a main pulmonary artery and the aorta.
II	Right and left pulmonary arteries arise directly and in close proximity from the posterior wall of the truncus.
III	Right and left pulmonary arteries arise from more widely separated orifices on the posterior truncal wall.
IV	Branch pulmonary arteries are absent. Pulmonary blood flow is derived from aorticopulmonary collaterals.

The anatomy of truncus arteriosus results in the obligatory mixing of systemic and pulmonary venous blood at the level of the VSD and truncal valve, which produces arterial saturations of 85% to 90%. The systemic arterial saturation depends on the volume of PBF, which in turn is determined by the PVR. As the PVR begins to fall, excessive pulmonary circulation ensues and leads to pulmonary congestion and signs and symptoms of CHF. This nonrestrictive left-to-right shunt may cause early development of irreversible pulmonary vascular obstructive disease.

The presence of truncal valve abnormalities poses further hemodynamic burdens. Truncal valve regurgitation leads to ventricular dilatation and low diastolic coronary perfusion pressures that can result in myocardial ischemia. Truncal valve stenosis promotes ventricular hypertrophy, increases the myocardial oxygen demand, and limits coronary and systemic perfusion, especially with the large volume of runoff into the pulmonary vascular bed.

Table 81-3 Van Praagh and Van Praagh Classification of Truncus Arteriosus

Type	Description
A	With a VSD
B	Without a VSD
1	The aortopulmonary septum is partially developed (partially separate main pulmonary artery).
2	The aortopulmonary septum is absent (no main pulmonary artery segment); both branch pulmonary arteries arise from the common trunk.
3	Either branch pulmonary artery is absent.
4	Hypoplasia, coarctation, atresia, or absence of the aortic isthmus is associated with a large PDA.

PDA, patent ductus arteriosus; VSD, ventricular septal defect.

Neonates with truncus arteriosus present with signs of CHF and collapsing peripheral pulses. Chest radiography shows marked cardiomegaly; pulmonary plethora, often with minimal thymus shadow; and a right aortic arch. The ECG most often depicts biventricular hypertrophy. Echocardiography is the diagnostic procedure of choice and can demonstrate the truncal vessel, the structure and function of the truncal valve, associated lesions such as interrupted aortic arch, and often the pulmonary arterial anatomy. Cardiac catheterization is not performed unless the anatomy is unclear, further information is needed about the status of the truncal valve, or the status of the pulmonary vasculature is unclear (i.e., infants older than 3 months at diagnosis).

The natural history of patients born with truncus arteriosus is early demise. Approximately 40% of infants are dead within 1 month, 70% by 3 months, and 90% by 1 year.⁸⁰ Early death is caused by CHF. Survivors may do well for a period of time until the development of pulmonary vascular obstructive disease and Eisenmenger syndrome. The ultimate treatment of truncus arteriosus is surgical correction in the neonatal period. Medical treatment is palliative and directed toward controlling CHF with fluid restriction, diuretics, digitalis, and afterload reduction. Complete repair entails separating the pulmonary arteries from the truncus, repairing the resulting defect in the aorta, closing the VSD, and restoring the continuity of the right ventricular outflow tract with an extracardiac conduit. Severe truncal valve regurgitation requires truncal valve repair⁸¹ or replacement, which is best done with a cryopreserved allograft. An associated interrupted aortic arch is repaired by constructing a primary end-to-end anastomosis of the distal ascending aorta with proximal augmentation if necessary.

The results of truncus arteriosus repair have improved greatly during the last two decades. Before the importance of early operation to avoid irreversible PVR was appreciated, patients underwent repair at most institutions at an average age of 2 to 5 years with high mortality rates. Ebert et al. showed that repair in the first 6 months of life is not only possible, but also preferable, reporting a mortality rate of 9%.⁸² Current hospital mortality for the neonatal repair of truncus arteriosus ranges between 4.3% and 17%, with the majority of deaths occurring in complex truncus arteriosus or in truncus arteriosus with associated severe truncal valve regurgitation.^{72-74,83-85} Risk factors for poor outcome identified in various studies include significant truncal regurgitation, need for truncal valve replacement, birth weight less than 2.5 kg, presence of interrupted aortic arch or coronary artery anomalies, pulmonary reconstruction with a technique other than valved heterograft or allograft, and age older than 100 days.^{72-74,83-87} Other recent studies have demonstrated that interrupted aortic arch has been neutralized as a risk factor.^{74,84}

AORTIC STENOSIS

AS refers to a form of left ventricular outflow tract obstruction that may occur at the valvar (70%), subvalvar (25%), or supra-valvar (5%) level (Fig. 81-9). AS occurs in about 4% of patients with congenital heart disease.⁷ The severity of AS may be graded by echocardiography or catheterization. Classification by echocardiography peak instantaneous pressure gradient is mild (<40 mm Hg), moderate (40 to 70 mm Hg), and severe (>70 mm Hg). Classification by catheterization peak-to-peak pressure gradient is mild (<30 mm Hg), moderate (30 to 50 mm Hg), and severe (>50 mm Hg).

Valvar AS occurs secondary to maldevelopment of the aortic valve. Most commonly, a bicuspid valve is present, although tricuspid and unicuspid valves are also represented. In valvar AS, the leaflets are thickened and frequently dysmorphic, and there is a variable degree of leaflet fusion along the commissures. The aortic annulus may be hypoplastic. In 20% of cases, valvar AS is associated with other

cardiac defects, most commonly coarctation of the aorta, PDA, VSD, or mitral stenosis. Males with valvar AS outnumber females by a ratio of 4:1. There is a wide spectrum of clinical presentation of valvar AS, but patients tend to present in one of two groups: younger patients (neonates and infants) with severe AS develop symptoms of rapidly progressive CHF, whereas older patients, with less severe obstruction at birth, have a more indolent course.

Figure 81-9. Anatomy of the types of congenital aortic stenosis. **A:** Valvar aortic stenosis. **B:** Supra-aortic stenosis and its repair (*inset*). **C:** Diffuse (tunnel) subvalvar aortic stenosis. **D:** Discrete subvalvar aortic stenosis.

Severe AS is usually well tolerated during fetal development. Although left ventricular output and antegrade flow across the aortic valve are decreased, the right ventricle compensates with increased output, and systemic perfusion is maintained by flow across the ductus. After birth, there is increased venous return to the left heart, and this exacerbates the pressure load created by the stenotic aortic valve, leading to left ventricular dysfunction. As the ductus closes during postnatal life, systemic malperfusion may develop with resulting hypotension, acidosis, and oliguria. Coronary perfusion is also impaired due to the combination of systemic hypotension and elevated left ventricular end-diastolic pressure. Patients with critical AS typically exhibit severe left ventricular dysfunction. These patients show signs of distress soon after birth. On examination, there is impaired distal perfusion with poor capillary refill and diminished, thready pulses. A systolic ejection murmur may be absent if the cardiac output is severely diminished. Differential cyanosis may be observed due to perfusion of the lower body with desaturated blood shunting through the ductus. The ECG shows left ventricular hypertrophy, and the chest radiograph displays cardiomegaly and pulmonary congestion. Echocardiography establishes the diagnosis.

Fetal echocardiography has allowed for early diagnosis of critical AS. For some, this may predict the progression to hypoplastic left heart syndrome or may result in irreversible left ventricular dysfunction. A few centers in the United States have been able to successfully balloon dilate the aortic valve in utero to promote left ventricular growth and preserve function in select cases.⁸⁸⁻⁹⁰

The neonate or infant with critical AS represents a true emergency. Endotracheal intubation and inotropic support are routine. Ductal patency is maintained with prostaglandins, and acidosis is corrected. All patients with critical AS require some form of urgent intervention. The approach is determined by the valve morphology and by the presence of associated defects. In its most extreme form, critical AS may be associated with underdeveloped left-sided cardiac chambers and therefore may represent a form of hypoplastic left heart syndrome. In these cases, single-ventricle palliation must be undertaken. For patients with adequate left-sided chambers, relief of AS may be achieved by one of the following three approaches: percutaneous balloon valvuloplasty, surgical valvotomy, or aortic valve replacement. Balloon valvuloplasty is generally considered the procedure of choice when the aortic

valve annulus is adequate and there are no associated cardiac defects. Alternatively, surgical valvotomy may be accomplished by closed or open techniques. The closed approach is performed using cardiopulmonary bypass, but without aortic cross-clamping. Dilators of increasing size are passed through a ventriculotomy in the left ventricular apex and advanced across the aortic valve. Some centers prefer open surgical valvotomy, which allows a precise valvotomy under direct vision, although aortic cross-clamping with cardioplegia is necessary and results are similar to transventricular dilation. In all cases, the goal of therapy is to relieve stenosis without creating excessive aortic insufficiency. Dramatic clinical improvement is expected following balloon or surgical valvotomy, and early survivals of greater than 80% have been reported regardless of approach.^{91,92} The incidence of aortic insufficiency is slightly higher following balloon valvotomy. In most cases, however, stenosis will recur and repeat valvotomy or aortic valve replacement will eventually be required. Aortic valve replacement is problematic in the neonate due to small patient size. In these cases, many consider the best valve replacement to be a pulmonary autograft (Ross procedure)⁹³ with enlargement of the aortic annulus (Konno aortoventriculoplasty).⁹⁴ The Ross–Konno procedure has been used successfully for neonates with critical AS in whom the aortic annulus is hypoplastic and for selected patients in whom valvuloplasty was unsuccessful. Survival following the Ross–Konno procedure in infants has been shown to be excellent.⁹⁵ Growth of the pulmonary autograft has been documented, thereby making it an ideal valve replacement for children. Unfortunately, as part of the Ross procedure, the pulmonary valve must be replaced using a cryopreserved homograft that does not grow, and homograft replacement must be anticipated at intervals as the patient grows.

In contrast to infants with critical AS, older children with valvar AS usually present with less severe stenosis (mild or moderate), and most are asymptomatic. Symptoms of angina, syncope, and CHF are not commonly reported. Congenital valvar AS is a progressive lesion, however, and survival is dependent on the severity of stenosis and the rate of its progression. Sudden cardiac death is the most common cause of mortality. Endocarditis occurs in less than 1% of patients. The diagnosis of valvar AS in older children can frequently be made on physical examination. There is a classic systolic crescendo–decrescendo murmur at the upper sternal border, which radiates to the neck. An ejection click is often present. A visible apical impulse is suggestive of significant left ventricular hypertrophy. In severe cases, the pulse may be weak and delayed (*pulsus tardus et parvus*). The ECG shows left ventricular hypertrophy. The chest radiograph is usually normal. Echocardiography accurately defines the level of stenosis and its severity. Using Doppler techniques, the pressure gradient across the stenotic valve may be estimated using a simplified form of Bernoulli's equation, $P = 4V^2$, where P is the pressure gradient and V is the peak flow velocity. Cardiac catheterization is generally reserved for therapeutic intervention.

All patients with severe valvar AS should undergo intervention, as should all symptomatic patients with moderate stenosis. Asymptomatic patients with mild or moderate stenosis are generally observed. As described previously for critical AS, the techniques used to relieve AS in older patients include percutaneous balloon valvuloplasty, surgical valvulotomy, and valve replacement. Balloon valvuloplasty is usually performed as the primary intervention, and is associated with a success rate of nearly 90% and a mortality of less than 1%.⁹⁶ Open surgical valvotomy is an alternative approach with similar results.⁹⁷ For valves that are severely dysplastic, develop restenosis after intervention, or become insufficient as a result of prior intervention, valve replacement may be necessary. For older children, there are more options for valve replacement. The choices include mechanical prostheses, bioprosthetic valves, and tissue substitutes, such as porcine xenografts, cryopreserved human allografts, and pulmonary autografts (Ross procedure). The mechanical valves are the most durable, but require chronic anticoagulation. The bioprosthetic and tissue valves do not require long-term anticoagulation, but tend to deteriorate over time (with the exception of the pulmonary autograft). The pulmonary autograft has the potential advantage of growth but the homograft used to replace the pulmonary valve will require replacement. Selection of the appropriate replacement valve is a complex decision that requires input from all involved parties.

Subvalvar AS occurs below the level of the aortic valve and may be discrete (80%) or diffuse (20%). Discrete (or membranous) subaortic stenosis is rarely seen in infants and tends to progress over time. This lesion consists of a crescentic or circumferential fibrous or fibromuscular membrane that protrudes into the left ventricular outflow tract. The pathogenesis of discrete subaortic stenosis is unknown, but it is thought to be an acquired lesion that develops secondary to a congenital abnormality of the left ventricular outflow tract in which abnormal flow patterns lead to endocardial injury with resultant fibrosis. Although the aortic valve leaflets are usually normal in discrete subaortic stenosis, the

turbulent flow created by the obstruction can cause leaflet thickening and progressive aortic insufficiency. Diffuse subaortic stenosis is a more severe form that creates a long, tunnel-like obstruction. Diffuse subaortic stenosis should be distinguished from hypertrophic cardiomyopathy. Both forms of subaortic stenosis are associated with a high risk of endocarditis. The clinical findings in subvalvar AS are similar to those for valvar stenosis.

Intervention for discrete subvalvar stenosis is usually undertaken when the gradient exceeds 30 to 50 mm Hg or when aortic insufficiency is present. In these patients, resection of the membrane is readily performed by a transaortic approach. To reduce the incidence of restenosis, we advocate concurrent performance of a septal myomectomy to alter the geometry of the left ventricular outflow tract.⁹⁸ Operative mortality approaches zero. The recurrence rate of discrete stenosis following membrane resection and myomectomy has been reported to be as low as 4%.⁹⁹ Complications associated with membrane resection can include heart block, VSD, or damage to the aortic or mitral valve leaflets.

The indications for operative intervention in diffuse subaortic stenosis are similar to those for valvar stenosis. When diffuse subaortic stenosis is associated with hypoplasia of the aortic annulus, repair is best achieved with a Konno aortoventriculoplasty, whereby an incision is carried across the aortic annulus and subjacent ventricular septum, the opening patched, and an aortic valve implanted. Patients with an adequate aortic annulus may undergo a septoplasty (modified Konno), in which the septal incision is confined to the immediate subvalvar area and a patch is used to widen the left ventricular outflow tract without replacing the aortic valve. Despite the technical complexity of repair for diffuse subaortic stenosis, excellent results have been reported with high survival and freedom from reoperation.¹⁰⁰

Supravalvar AS is characterized by thickening of the wall of the ascending aorta. The lesion may be localized (80%) to the region of the sinotubular ridge (at the level of the valve commissures), creating an hourglass deformity, or it may be more diffuse (20%), extending into the aortic arch and its branches. In both varieties, the aortic valve leaflets may be abnormal. The free edges of the aortic valve leaflets may adhere to the aortic wall in the region of intraluminal thickening, and this may lead to reduced coronary blood flow during diastole. Aortic wall thickening may also extend into the coronary ostia and further impair coronary blood flow. Associated cardiac lesions are common, particularly branch PA stenoses. A genetic basis for supravalvar AS has been established.¹⁰¹ About 50% of cases of supravalvar AS are associated with Williams syndrome, in which a partial deletion of chromosome 7 (including the elastin gene) leads to the triad of supravalvar stenosis, mental retardation, and a characteristic “elfin” facies. Isolated mutations in the elastin gene have also been shown to produce familial supravalvar AS with an autosomal dominant pattern of transmission. There is a significant incidence of endocarditis in patients with supravalvar AS. Sudden death is frequently reported and is probably related to coronary obstruction.

The signs and symptoms of supravalvar AS are similar to those in other forms of left ventricular outflow tract obstruction. The diagnosis is made by echocardiography, but cardiac catheterization (and more recently magnetic resonance imaging [MRI]) is essential to define the aortic, coronary, and pulmonary arterial anatomy prior to surgical intervention.

Operative intervention is indicated for patients with supravalvar AS in whom the gradient exceeds 50 mm Hg. A number of operations have been proposed for the treatment of localized supravalvar stenosis. The classic repair involves a longitudinal incision across the obstruction in the ascending aorta, which is extended into the noncoronary sinus. The thickened, hypertrophic ridge is resected by endarterectomy and the aortotomy is augmented with an elliptical patch. A variation of this repair involves creation of an inverted-Y aortotomy with one limb of the Y extended into the noncoronary sinus and the other into the right coronary sinus. A Y-shaped patch is then used to augment the aortotomy. Finally, the Brom repair is performed by transection of the ascending aorta beyond the supravalvar ridge. Separate incisions are then made through the supravalvar ridge into each sinus of Valsalva. Triangular patches are placed to augment each of these incisions, thereby relieving the supravalvar obstruction. Reconnection of the aortic root to the ascending aorta completes the repair. The repair of the diffuse type of supravalvar stenosis is performed under circulatory arrest with extensive patching of the ascending aorta, transverse arch, and involved arch arteries. Branch pulmonary stenoses are best managed using transcatheter techniques.

The results of surgery for localized supravalvar AS are generally good with low operative mortality and excellent long-term survival.¹⁰²⁻¹⁰⁴ The diffuse form is more difficult to treat, and recurrence is more likely. Overall results are much worse when severe bilateral PA stenoses are present.

COARCTATION OF THE AORTA

Coarctation of the aorta is a narrowing of the proximal descending thoracic aorta distal to the origin of the left subclavian artery, near the insertion of the ductus arteriosus (or ligamentum arteriosum). The severity of luminal narrowing and the length of the aorta affected are variable. Coarctation is thought to occur as a result of ectopic tissue from the ductus arteriosus, which migrates into the wall of the adjacent aorta. After birth, as the ductus closes, the ectopic tissue in the aorta also constricts. Frequently, a posterior shelf of tissue is present at the point of most severe obstruction. The aortic obstruction caused by coarctation creates a pressure load on the LV.

The incidence of coarctation is about 0.5 per 1,000 live births, and its prevalence is 5% of congenital heart defects.⁷ Coarctation is commonly associated with other heart defects including bicuspid aortic valve (in more than 50% of cases), PDA, and VSD. Other left-sided obstructive lesions may also be present, such as aortic arch hypoplasia, AS, mitral stenosis, and left ventricular hypoplasia. Coarctation is also recognized to occur in association with Turner syndrome.

Patients with severe coarctation present in the newborn period. Aortic obstruction is so significant that perfusion of the lower body is dependent on flow from the ductus arteriosus. Spontaneous ductal closure typically worsens the aortic obstruction and may lead to malperfusion of tissues distal to the coarctation. The pressure load on the LV may precipitate CHF. Patients may develop shock with severe acidosis, oliguria, and diminished distal pulses. Infants with severe coarctation will generally not survive without intervention.

⁷ Older children with coarctation are usually asymptomatic. The diagnosis is commonly made on the basis of hypertension in the upper extremities with decreased pulses in the lower extremities. Noninvasive blood pressure measurements in all four extremities help to quantify the severity of aortic obstruction. These older patients tend to develop extensive collateral arteries that bypass the obstruction. Life expectancy for these patients is limited due to the development of heart failure later in life. Other long-term complications of coarctation include chronic hypertension, endocarditis (frequently involving a bicuspid aortic valve), endarteritis (in the poststenotic area of the aorta at the site of the jet of turbulent flow), aortic dissection, aortic aneurysm, and intracranial hemorrhage (from Berry aneurysms, which occur more commonly in patients with coarctation).¹⁰⁵

The diagnosis of coarctation can usually be made clinically. The infant with significant coarctation is frequently asymptomatic at birth, but following closure of the ductus develops signs of heart failure such as irritability, tachypnea, and poor feeding. Lower extremity pulses are absent, and upper extremity pulses may be weak. Chest radiography shows cardiomegaly and pulmonary venous congestion. There is a left ventricular strain pattern on the ECG. Echocardiography is usually diagnostic, demonstrating narrowing of the aorta at the coarctation site with a loss of pulsatility in the descending aorta.

In older children and adults with coarctation, there is usually a pressure gradient between the arms and legs, which can be demonstrated by measuring cuff pressures in all four extremities. On chest radiography, rib notching may be evident, secondary to erosion of the inferior rib borders from the development of large intercostal collateral vessels. Echocardiography usually confirms the diagnosis. Anatomic details may also be clarified with computed tomography (CT) and MRI. Cardiac catheterization is usually not necessary.

Generally, all patients with coarctation should undergo surgical repair. For neonates, the acute medical management includes initiation of PGE₁ for the purpose of reopening the ductus; this maneuver partially relieves the aortic obstruction and augments perfusion of the lower body due to improved antegrade flow across the arch, as well as right-to-left flow across the ductus. Prostaglandins are usually effective for reopening the ductus when initiated within 7 to 10 days of life, but are less successful thereafter.

Surgical repair of coarctation is usually performed through a left posterolateral thoracotomy via the third or fourth intercostal space. Neonates with an associated hypoplastic aortic arch may require sternotomy for extended arch augmentation with either primary extended end-to-end repair or patch augmentation. For repair via thoracotomy, the descending thoracic aorta, ductus (or ligamentum), transverse aortic arch, and brachiocephalic vessels are mobilized. Care is taken to preserve the vagus nerve and its recurrent laryngeal branch. The preferred surgical approach to coarctation in infants and children is a resection with end-to-end anastomosis or extended end-to-end repair if there is associated mild distal arch hypoplasia.¹⁰⁶ In older children and adults, it may not be possible to perform a resection with primary repair without creating excessive tension on the anastomosis, which may lead to hemorrhage or scarring with recurrent coarctation. An alternative strategy is necessary in these cases.

Patch aortoplasty may be performed in children in whom further growth is anticipated.^{107,108} The subclavian flap repair augments the narrowed aorta using native arterial tissue. Blood flow to the left arm is maintained by collateral vessels, although long-term studies have demonstrated a slight discrepancy in limb length in some patients. Prosthetic patch material may also be used. By avoiding circumferential prosthetic material, growth potential of the native aorta is preserved. The disadvantage of patch repair is a high risk of aneurysm formation. In adults, in whom growth is no longer a concern, resection of the coarctation may be performed with subsequent placement of a prosthetic interposition graft (either Dacron or polytetrafluoroethylene).

One of the principal concerns during coarctation repair is interruption of distal aortic blood flow, especially to the spinal cord. The anterior spinal artery is fed by major radicular branches from intercostal arteries. In patients without well-formed collaterals, ischemia of the spinal cord may be precipitated by aortic cross-clamping, and paraplegia may result. Protective measures include induction of mild hypothermia, maintenance of a high proximal aortic pressure, and minimization of cross-clamp time. In older patients, distal aortic perfusion may be maintained by the technique of left heart bypass, in which oxygenated blood is taken from the left atrium and delivered to the femoral artery or distal aorta using a centrifugal pump.¹⁰⁹ This is usually not necessary due to the presence of significant collaterals. Overall, the incidence of paraplegia following coarctation repair is less than 1%.¹¹⁰

Following repair, patients may develop severe hypertension. This can be managed using intravenous beta blockers (e.g., esmolol). Uncontrolled hypertension can lead to the complication of mesenteric arteritis. Hypertension usually resolves within days to weeks after repair, although older children and adults may require lifelong antihypertensive therapy. Repair of coarctation during infancy is thought to minimize the risk of late hypertension.¹¹¹

Transcatheter intervention for primary therapy of discrete coarctation in young children and adolescents remains controversial. Technical success rates range from 80% to 98%, with reintervention rates of 10% to 20%.^{112–114} Placement of a stent has been associated with higher success rates and lower restenosis rates¹¹⁴; however, the long-term outcome of stents in this population remains unknown, and stents are not an ideal option in younger children. There is no evidence to date, therefore, that demonstrates superiority or equivalence of catheter intervention compared to surgery. In addition, there is a high complication rate of 5% to 11.7%, including recurrent coarctation, need for multiple interventions, injury to the femoral vasculature (for access), aortic dissection, and aneurysm formation.^{113,115–117} On the other hand, balloon angioplasty is widely accepted for the treatment of recurrent coarctation following surgery, in which the success rate is on the order of 90% with low recurrence rates.^{118–120}

The early mortality following repair of coarctation in neonates is 2% to 10%, whereas the risk in older children and adults is about 1%.^{106,121} The incidence of recurrent coarctation following resection and end-to-end repair is about 4% to 8%.^{106,122,123} The long-term survival following repair of coarctation is determined by the presence of associated defects and the persistence of hypertension.

PATENT DUCTUS ARTERIOSUS

The ductus arteriosus is a normal fetal vascular structure that allows blood from the right ventricle to bypass the high-resistance pulmonary vascular bed and pass directly to the systemic circulation. The ductus communicates between the main PA (or proximal left PA) and the proximal descending thoracic aorta. Histologically, the media of the ductus contains a predominance of smooth muscle cells, whereas the media of the aorta and PA contain well-developed elastic fibers. Vasocontrol of the ductus is mediated by two important mechanisms: oxygen tension and prostaglandin levels. During fetal development, low oxygen tension and high levels of circulating prostaglandin maintain ductal patency. During the final trimester, the ductus becomes less sensitive to prostaglandins and more sensitive to the effects of oxygen tension. Following birth, the rise in oxygen tension and a fall in prostaglandins (which were previously supplied principally by the placenta) lead to ductal closure, which is usually complete by 12 to 24 hours. After closure, the ductus becomes a fibrous cord known as the ligamentum arteriosum. Failure of closure of the ductus leads to the condition called PDA. PDA occurs in about 1 out of 1,200 live births and accounts for 7% of congenital heart defects.⁷ The incidence is much higher in premature infants (>20%).¹²⁴ This elevated incidence is thought to be related to immaturity of the ductal wall resulting in impaired sensitivity to oxygen tension.

PDA may occur as an isolated defect, or it may occur in association with a number of other anomalies. Patency of the ductus arteriosus is desirable in a number of defects in which there is either inadequate

PBF (such as pulmonary atresia) or inadequate systemic blood flow (as in severe coarctation of the aorta). The discovery that extrinsic delivery of prostaglandins can maintain ductal patency has played a critical role in improving the survival of these patients.¹²⁵

The physiologic manifestation of PDA is shunting of blood across the ductus. The shunt volume is determined by the size of the ductus and by the ratio of pulmonary to systemic vascular resistance. At birth, the PVR drops dramatically and continues to decline over the first several weeks of life. As a result, shunting across a PDA is from left to right. Excessive PBF can lead to CHF. In extreme cases, hypotension and systemic malperfusion may result. Patients with a large PDA who survive infancy tend to develop pulmonary vascular obstructive disease. Eisenmenger physiology results when the PVR exceeds the systemic vascular resistance, producing a reversal of shunting across the ductus to right to left. This leads to cyanosis and, eventually, right ventricular failure. Small PDAs may persist to adulthood without producing any symptoms or physiologic derangement. Endocarditis and endarteritis have been reported as long-term complications of PDA.¹²⁶

In patients with PDA, symptoms are proportional to the shunt volume and the presence of associated defects. Left-to-right shunting produces volume overload of the left heart. Infants with CHF demonstrate symptoms of tachypnea, tachycardia, and poor feeding. Older children may present with recurrent respiratory infections, fatigue, and failure to thrive. Physical findings include a widened pulse pressure and a continuous “machinery” murmur heard best along the left upper sternal border. Chest radiography shows increased pulmonary vascular markings and left heart enlargement. Left ventricular hypertrophy and left atrial enlargement may be evident on the ECG. Echocardiography is the diagnostic method of choice. Diagnostic cardiac catheterization is performed only in older patients with suspected pulmonary hypertension to evaluate for pulmonary vascular obstructive disease. More frequently, catheterization is utilized for transcatheter occlusion of the ductus in selected cases.

PDA closure is performed for all symptomatic patients. Closure is also recommended for asymptomatic patients due to the risk of heart failure, pulmonary hypertension, and endocarditis. Closure of the ductus may be accomplished by one of three approaches: pharmacologic, surgical, and endovascular. Indomethacin and ibuprofen, which are cyclooxygenase inhibitors, stimulate PDA closure in premature infants.^{127,128} Both are rarely effective in full-term infants. Due to improved side effect profile of gastrointestinal bleeding and renal dysfunction, ibuprofen is the current drug of choice.¹²⁸ The dosing regimen is 10 mg/kg intravenously, followed by 5 mg/kg intravenously at 24-hour intervals for a total of three doses. This is effective in about 70% to 80% of premature babies.^{128,129} Due to their side effects, indomethacin and ibuprofen are contraindicated in patients with sepsis, renal insufficiency, intracranial hemorrhage, or bleeding disorders. Failure of ibuprofen after two complete courses results in referral for surgical closure.

The surgical approach to PDA is through a left posterolateral thoracotomy via the third or fourth intercostal space. The pleura is incised over the proximal descending thoracic aorta. This allows medial retraction of the vagus nerve. The recurrent laryngeal nerve curves behind the ductus and should be protected throughout the procedure. Dissection is then performed to demonstrate the pertinent anatomy. In many cases, the ductus is the largest vascular structure present, and it must not be confused with the aorta. Ductal tissue is extremely friable, so direct manipulation is minimized. In premature infants, the ductus is controlled with a single surgical clip; this procedure is commonly performed in the neonatal intensive care unit, thereby avoiding problems associated with patient transfer.^{130,131} In older patients, occlusion of the ductus is achieved with simple silk ligature, or, preferably, by division between ligatures to minimize recurrence.

Thoracoscopic techniques have been developed to perform PDA ligation.¹³² This approach has the potential benefits of decreased pain and quicker recovery. Disadvantages include a substantial learning curve and increased operating time.

A number of endovascular devices have been developed for the purpose of transcatheter occlusion of the PDA.^{133–135} This approach is very successful in older infants, children, and adults with small and moderate-sized PDAs and has become the treatment of choice at many centers. Surgical therapy is reserved for PDAs having a large diameter or very short length.

Rarely, an adult will present with a significant PDA. These patients must be carefully evaluated for the presence of pulmonary vascular obstructive disease prior to ductal closure. If the patient is not a candidate for device closure, surgical closure can be problematic. Calcification of the ductal wall is common in adults, making ligation hazardous. In some cases, cardiopulmonary bypass may be required with closure of the ductus from within the PA.^{136,137}

Closure of the ductus by surgical or transcatheter techniques is achieved with a mortality that

approaches zero.¹³⁰ Potential complications include pneumothorax, phrenic nerve injury, recurrent laryngeal nerve injury, and chylothorax (from injury to the thoracic duct). Long-term survival should be normal following PDA ligation in most patients. Survival in premature infants depends primarily on the extent of prematurity with its attendant complications.

VASCULAR RINGS

Vascular rings comprise a spectrum of vascular anomalies of the aortic arch, pulmonary artery, and brachiocephalic vessels. The clinically significant manifestation of these lesions is a varying degree of tracheoesophageal compression. These vascular anomalies can be divided into complete vascular rings and partial vascular rings. Incomplete vascular rings include aberrant right subclavian artery, innominate artery compression, and pulmonary artery sling. The incidence of clinically significant vascular rings is 1% to 2% of all congenital heart defects.⁷

Vascular rings and pulmonary slings have been described in conjunction with other cardiac defects, including TOF, ASD, branch pulmonary artery stenosis, coarctation, AVSD, VSD, interrupted aortic arch, and aortopulmonary window. Significant associated cardiac anomalies occur in 11% to 20% of patients with a vascular ring.^{138,139} A right aortic arch is generally associated with a greater incidence of coexisting anomalies.

By the end of the fourth week of embryonic development, the six aortic or branchial arches have formed between the dorsal aortae and ventral roots. Subsequent involution and migration of the arches results in the anatomically normal or abnormal development of the aorta and its branches. The majority of the first, second, and fifth arches regress. The third arch forms the common carotid artery and proximal internal carotid artery. The right fourth arch forms the proximal right subclavian artery. The left fourth arch contributes to the portion of the aortic arch from the left carotid to left subclavian arteries. The proximal portion of the right sixth arch becomes the proximal portion of the right pulmonary artery, while the distal segment involutes. Similarly, the proximal left sixth arch contributes to the proximal left pulmonary artery, and the distal sixth arch becomes the ductus arteriosus.

Children with a complete vascular ring generally present within the first weeks to months of life. Typically, children with a double aortic arch present earlier in life than those with a right arch and retroesophageal left ligamentum. In the younger age group, respiratory symptoms predominate, as liquids are generally well tolerated. Respiratory symptoms may include stridor, nonproductive cough, apnea, or frequent respiratory infections. The cough is classically described as a “seal bark” or “brassy.” These symptoms may mimic asthma, respiratory infection, or reflux, and children with vascular rings are often initially misdiagnosed. With the transition to solid food, dysphagia becomes more apparent.

The presentation of a patient with an incomplete vascular ring is variable. Children with innominate artery compression usually present within the first 1 to 2 years of life with respiratory symptoms. Aberrant right subclavian artery is the most common arch abnormality, occurring in approximately 0.5% to 1% of the population, and it rarely causes symptoms. Classically, when symptoms do occur, they present in the seventh and eighth decades, as the aberrant vessel becomes ectatic and calcified, causing *dysphagia lusoria* due to impingement of the artery on the posterior esophagus.

Children with pulmonary artery slings generally present with respiratory symptoms within the first few weeks to months of life. As with complete rings, respiratory symptoms may include stridor, nonproductive cough, apnea, or frequent respiratory infections and may mimic other conditions, leading to misdiagnosis. Pulmonary artery slings are associated with complete tracheal rings in 30% to 40% of patients, leading to focal or diffuse tracheal stenosis.

The methods for diagnosing a vascular ring are variable, due to the variability in presentation and the spectrum of diagnostic tests available. A child with a presumptive diagnosis of asthma or tracheomalacia may be referred to a pulmonologist and a diagnosis of vascular ring made or suspected initially by chest radiograph and bronchoscopy. In some situations, the diagnosis is made by echocardiography during evaluation for concurrent cardiac defects. Regardless, the diagnosis generally begins with a chest radiograph. Complementary studies may include barium esophagogram, CT, MRI, and bronchoscopy. CT, MRI, and bronchoscopy are important modalities to define the tracheal anatomy in a patient with a pulmonary artery sling. Echocardiography may be diagnostic, and may be used to rule out other cardiac anomalies. Tracheograms and cardiac catheterizations, which have been used extensively in the past, are rarely currently indicated.

A double aortic arch occurs when the distal portion of the right dorsal aorta fails to regress. The two arches form a complete ring, encircling the trachea and esophagus. The right arch is dominant in the

majority of the cases, followed by left dominant, with codominant arches being the least common. The left and right carotid and subclavian arteries generally arise from their respective arches. The ligamentum arteriosum and descending aorta usually remain on the left.

The approach to repair of a double aortic arch is via a left posterolateral thoracotomy. The pleura is incised, after identifying the vagus and phrenic nerves. The ligamentum or ductus arteriosum is divided while preserving the recurrent laryngeal nerve. The nondominant arch is then divided between two vascular clamps at the point where brachiocephalic flow is optimally preserved. If there is concern regarding the location for division, the arches can be temporarily occluded at various points while monitoring pulse and blood pressure in each limb. If there is an atretic segment, the division is done at the point of the atresia. Dissection around the esophagus and trachea in the regions of the ligamentum/ductus and nondominant arch allows for retraction of the vascular structures and lysis of any residual obstructing adhesions.

The surgical approach for a right aortic arch with retroesophageal left ligamentum arteriosum is the same as for a double arch. The ligamentum is divided and any adhesions around the esophagus and trachea are lysed. Rarely, the Kommerell diverticulum has been reported to cause compression even after division of the ligamentum. As such, it may be prudent to resect or suspend the diverticulum posteriorly.

In innominate artery compression syndrome, the aortic arch and ligamentum are in their normal leftward position. However, the innominate artery arises partially or totally to the left of midline. As the artery courses from left to right anterior to the trachea, it causes tracheal compression. The symptoms of innominate artery compression may be mild to severe. With mild symptoms and minimal tracheal compression on bronchoscopy, children can be observed expectantly as the symptoms may resolve with growth. Indications for surgery include apnea, severe respiratory distress, significant stridor, and recurrent respiratory tract infection. Several approaches for the correction of innominate artery compression syndrome have been described. These include simple division, division with reimplantation into the right side of the ascending aorta, and suspension to the overlying sternum.

An aberrant right subclavian artery occurs when there is regression of the right fourth arch between the right common carotid and right subclavian arteries. The right subclavian then arises from the leftward descending aorta, laying posterior to the esophagus as it crosses from left to right. Although the artery can compress the esophagus posteriorly, it is rarely the cause of symptoms in children. Surgical treatment involves simple division via a left posterolateral thoracotomy. Rarely, reimplantation or grafting from the right carotid or aortic arch may be necessary.

Normally, the right and left sixth aortic arches contribute to the proximal portions of their respective pulmonary arteries. If the proximal left sixth arch involutes and the bud from the left lung migrates rightward to meet the right pulmonary artery, a pulmonary artery sling is formed. Pulmonary artery slings are associated with complete tracheal rings and tracheal stenosis in 30% to 40% of patients.

Initial attempts at the repair of a pulmonary artery sling involved reimplantation after division of the left pulmonary artery (LPA) and translocation of the trachea without cardiopulmonary bypass. These early reports had a high incidence of LPA thrombosis. This has led some authors to advocate division of the trachea and translocation of the LPA. This approach would seem sensible if the trachea were being divided in the course of tracheal reconstruction. However, currently most authors advocate the reimplantation of the LPA, which has resulted in excellent results. The procedure is done via a median sternotomy on cardiopulmonary bypass to ensure optimal visualization of the repair. Aortic cross-clamping is not necessary. The LPA is divided off of the right pulmonary artery, translocated anterior to the trachea, and reimplanted into the main pulmonary artery.

Any necessary reconstruction of the trachea is done concurrently with bronchoscopic assistance. Many techniques for tracheal reconstruction have been described, the most common of which are resection with primary reanastomosis and sliding tracheoplasty for short-segment stenosis, and rib cartilage or pericardial patch for long areas of narrowing.¹⁴⁰

Over 95% of vascular rings without concurrent cardiac defects can be performed through a left thoracotomy. A right thoracotomy is indicated for the rare cases where there is a right ligamentum arteriosum. In addition, a double aortic arch with an atretic segment proximal to the right carotid artery is more easily divided through a right thoracotomy. The approach to these anomalies is the same as for a left-sided ring division, with the caveat that the right recurrent laryngeal nerve will loop around the right ligamentum.

Repair of vascular rings has been described using video-assisted thoracoscopic surgery (VATS) both with and without robotic assistance. Candidates for thoracoscopic division are limited to those patients

requiring only the division of nonpatent vascular structures. In general, VATS is used for patients greater than 15 kg due to current size limitations of the instruments.¹⁴¹

Mortality for the repair of a vascular ring is 0% to 4%, with improved survival occurring in more recent series.^{138,139,142} The majority of deaths are related to other cardiac defects or respiratory infection and failure. Backer et al. reported a series of 16 patients repaired utilizing LPA division and reimplantation for pulmonary artery sling, all of whom also required tracheal reconstruction. There were no operative mortalities and one late death due to respiratory complications.¹⁴⁰ The major source of morbidity, as well as mortality, in this and other series is related to the tracheal reconstruction.

CORONARY ARTERY ANOMALIES

Coronary artery anomalies occur in 0.3% to 1.3% of the population.^{143,144} They can be classified as minor, secondary, or major based on their clinical significance.¹⁴⁵ Minor defects have no functional significance and are usually detected as incidental findings at cardiac catheterization. Secondary defects have no intrinsic significance, but alter surgical management when they are present. An example of a secondary defect is an anomalous origin of the left anterior descending artery from the right coronary artery that crosses the hypoplastic infundibulum in a patient with TOF. The presence of this vessel may prevent the safe performance of a transannular incision and thereby mandate the use of a conduit. Major defects are the most important form of coronary anomaly, because they exert an intrinsically adverse effect on the myocardium. Major anomalies can be subdivided based on anatomy: coronary arteriovenous fistula, anomalous pulmonary origin of a coronary artery, anomalous aortic origin of a coronary artery, myocardial bridging, or coronary artery aneurysm.

8 Coronary arteriovenous fistula is the most common major coronary anomaly. An abnormal connection exists between a coronary artery (usually the right) and another vascular structure (usually one of the right heart chambers). Most fistulas are isolated and solitary. The fistula leads to left-to-right shunting, which can produce CHF. Other symptoms include angina, endocarditis, myocardial infarction, arrhythmia, and sudden death. The diagnosis is suggested by echocardiography and confirmed by catheterization. All symptomatic fistulas should be occluded, either surgically or by transcatheter techniques. In some cases, coronary bypass grafting may be necessary when distal flow is compromised by fistula occlusion. Treatment of asymptomatic fistulas is controversial, but occlusion should probably be undertaken when significant left-to-right shunting is present.

The second most common major coronary anomaly is origin of a coronary artery from the PA. The most common manifestation is the anomalous left coronary artery arising from the pulmonary artery (ALCAPA). The right coronary (or both coronaries) may also arise anomalously from the PA, but only in very rare cases. ALCAPA is usually well tolerated during fetal development, but after birth, the pulmonary systolic pressure usually drops (following ductal closure and decline in PVR) and the anomalous coronary is perfused with desaturated blood at low pressure. Collateral vessels develop between the normal right coronary artery and the abnormal left coronary, but the benefit is negated due to the development of coronary steal, whereby the collateral blood shunts left to right by retrograde flow in the anomalous coronary into the low-pressure PA. Most patients will present between 6 weeks and 3 months of life. Typical symptoms include irritability, difficulty in feeding, and other signs of CHF. Untreated, ALCAPA is nearly always fatal. Rarely, patients will survive to adulthood and present with symptoms of angina or sudden death. On examination, patients with ALCAPA frequently have a holosystolic murmur of ischemic mitral regurgitation. The pulmonary component of the second heart sound may be pronounced due to pulmonary hypertension. Chest radiography is significant for cardiomegaly and pulmonary edema. Electrocardiographic evidence of ischemia and infarction is usually present. Echocardiography is usually diagnostic and is useful for assessing the severity of left ventricular dysfunction and ischemic mitral regurgitation, which are commonly present. Catheterization is occasionally necessary to clarify the anatomy, but this technique is used less frequently due to the risk of inducing life-threatening arrhythmias.

Surgical repair is indicated for all patients with ALCAPA. Historically, the initial surgical approach involved ligation of the proximal left coronary artery. This served to eliminate coronary steal and allow perfusion of the left coronary system by collaterals from the right. Despite the ease of simple ligation, most centers have abandoned this approach in favor of establishment of a two-coronary system, which offers better long-term freedom from ischemia. In older patients, this may be achieved by proximal ligation of the left coronary artery in conjunction with coronary artery bypass, ideally with a left internal mammary graft. Coronary bypass is technically difficult in neonates, and a number of

alternative operations have been devised to create a direct connection between the aorta and the anomalous coronary artery. Most commonly, this can be achieved by removing the origin of the left coronary artery (along with a button of adjacent PA) and reimplanting the vessel directly into the side of the aorta. Another approach involves creation of a side-to-side connection between the aorta and PA with placement of an intrapulmonary baffle to direct flow from this connection to the anomalous left coronary ostium. With improved coronary transfer techniques learned from the arterial switch operation, direct reimplantation of the anomalous coronary artery is always feasible and preferred. Survival following surgical repair of ALCAPA has improved over the years.¹⁴⁶ Recent reports have suggested an operative mortality of 6% or less.^{147,148} Ventricular function tends to normalize after surgery.¹⁴⁹ In most patients, mitral valve function also improves,^{147,149} but for patients with severe mitral regurgitation, concurrent mitral valve repair may rarely be indicated.

Anomalous aortic origins of the coronary arteries are usually minor defects, but a potentially dangerous abnormality exists when the left main coronary artery arises from the right coronary sinus and passes between the PA and aorta. This defect has been associated with cardiac symptoms and sudden death, as has the origin of the right coronary artery from the left coronary sinus (usually when the right coronary is dominant).^{150,151} The etiology of ischemia in both defects is thought to be related to the acute angle of origin and slit-like orifice of the anomalous vessel often with an intramural course and the extrinsic compression created by the opposing walls of the aorta and PA. These defects usually present in older patients. Symptomatic patients are treated surgically by unroofing the coronary ostia into the aorta or by coronary artery bypass.

Myocardial bridging occurs when a segment of an epicardial coronary artery (usually the left anterior descending) takes an intramyocardial course over a short segment. Although this is a common incidental finding at cardiac catheterization, this defect has been associated in some cases with myocardial ischemia. Treatment involves dividing the muscle bridge to free the coronary, coronary bypass beyond the bridge, or transcatheter stenting.

Coronary aneurysms occur rarely, usually in conjunction with an inflammatory condition such as Kawasaki syndrome, polyarteritis nodosa, Takayasu arteritis, or syphilis. Coronary aneurysms may thrombose or lead to distal coronary stenosis or embolization. Rupture occurs uncommonly. Treatment ranges from antiplatelet therapy to coronary bypass grafting.

UNIVENTRICULAR HEART

In the univentricular heart, only one ventricular chamber is connected to the atria. To be classified as a ventricle, a chamber must receive at least half of an inlet valve. In the most common form of univentricular heart, both the mitral and tricuspid valves connect to a morphologic LV (double-inlet LV), which ejects blood through a hypoplastic outlet chamber and then, due to malposition of the great arteries, to the aorta. The outlet chamber is not considered to be a ventricle, regardless of its size, because it does not receive an inlet valve. Similarly, the intracardiac communication is not termed a VSD, but a bulboventricular foramen. Univentricular hearts are frequently associated with malpositions of the great vessels and varying degrees of obstruction to PBF. In double-inlet LV, the aorta is usually anterior and to the left of the PA.

The presentation of infants with univentricular heart is variable, depending on the amount of PBF.¹⁵² When the pulmonary flow is excessive, cyanosis may be mild, and the dominant feature is CHF. Associated PS decreases the PBF, and the degree of cyanosis is increased. Associated lesions may further complicate the picture, such as coarctation, subaortic stenosis, or a restrictive ASD. Patients with moderate PS may achieve a well-balanced circulation with acceptable systemic oxygenation and normal PA pressure. These patients may be symptom-free well into adolescence. Most patients, however, require intervention early in life to reduce excessive PBF or to increase it in the presence of significant PS. Pulmonary vascular obstructive disease develops early when PBF is excessive. With the possible exception of patients in whom the pulmonary and systemic blood flow is well balanced, the prognosis for patients with unoperated univentricular hearts is poor, with more than half dying early of CHF or dysrhythmias.

In the presence of excessive PBF and pulmonary hypertension, operation should be performed early in life to control PBF and prevent the development of pulmonary vascular occlusive disease. Options include PA banding or division of the main PA in conjunction with a controlled aortopulmonary shunt. PA banding is a less complicated procedure; however, it is often difficult to adjust the pulmonary flow accurately, and too proximal or too distal a band can lead to distortion of the pulmonary valve or

branch pulmonary arteries, which further complicates later operations. Simple division of the PA with placement of a modified Blalock–Taussig shunt can be undertaken in the presence of an adequate bulboventricular foramen providing unobstructed flow to the aorta. This option avoids the problems associated with a PA band, and more accurately controls the PBF. Another similar technique is division of the main PA, side-to-side anastomosis of the proximal PA with the native aorta, and placement of a modified Blalock–Taussig shunt (modified DKS procedure). It is not uncommon for the bulboventricular foramen to decrease in size over time due to progressive ventricular hypertrophy. Maintaining continuity from both the outlet chamber and the LV eliminates the possibility of subaortic obstruction, which can occur when the systemic blood flow depends entirely on egress through a bulboventricular foramen. In infants who are well balanced and can be safely managed medically until the age of 4 to 6 months, a hemi-Fontan or bidirectional Glenn, in which the superior vena caval flow is directed into the pulmonary arteries, can be used to increase the effective PBF. This procedure maximizes pulmonary flow without causing a volume overload to the single ventricle. It is most commonly used as part of an interim stage to a complete atriopulmonary connection or Fontan procedure.

The ultimate goal of surgical correction in patients with a univentricular heart is the total diversion of all vena caval blood directly into the pulmonary arteries. The Fontan procedure was first successfully performed in a patient with tricuspid atresia, but has since evolved as an excellent way to establish physiologic repair for patients with more complex forms of univentricular heart.¹⁵³ The superior vena caval blood returns directly via an end-to-side anastomosis with the PA (bidirectional Glenn) or through a right atrial–PA connection (hemi-Fontan). The inferior vena caval flow is directed to the PA with an intra-atrial baffle (lateral tunnel technique, [Fig. 81-10](#)) or an extracardiac conduit. All oxygenated pulmonary venous flow empties into the ventricular chamber through the AV valves to be ejected to the systemic circulation, while superior and inferior vena caval blood flows directly to the lungs to acquire oxygen prior to returning to the heart. For the Fontan procedure to be performed with a low operative mortality and an acceptable functional result, certain criteria must be met. Normal PA pressure (<20 mm Hg) and PVR (<2 Woods units/m²) are the most important prerequisites. Additionally, it is essential that ventricular function and AV valve function be normal. Many of the criteria originally proposed, including normal cardiac rhythm, right atrial hypertrophy, normal systemic venous return, and age older than 4 years, are of little or no importance in the current era. Although the Fontan procedure cannot be considered a truly corrective operation, it offers benefits that cannot be equaled by any of the other palliative procedures. The major advantages include restoration of normal systemic oxygen saturation and reduction of ventricular volume overload.

Figure 81-10. Total cavopulmonary connection for univentricular heart. The internal orifices of the superior and inferior venae

cavae are connected in the right atrium with a patch cut of polytetrafluoroethylene. The superior vena cava is divided just above its junction with the right atrium, and both ends are anastomosed to the right pulmonary artery. The main pulmonary artery is ligated.

Figure 81-11. Steps in the Norwood procedure for hypoplastic left-heart syndrome. **A:** Cannulation for bypass. **B:** Division of pulmonary artery and ductus arteriosus. **C:** Aortic arch opened from the origin to beyond the ductus. **D:** Pulmonary allograft used to enlarge arch and connect to the ventricle. **E:** Completed repair.

Ventricular septation procedures have also been successfully performed in patients with univentricular hearts. The subset of patients with a double-inlet LV, anterior and leftward aorta, nonrestrictive outlet foramen, and mild or no PS are best suited for septation. This anatomy allows placement of a relatively direct and straight prosthetic patch in the ventricle that separates the pulmonary and systemic circulations. The septation procedure has been associated with a relatively high morbidity, primarily related to complete heart block, so that its overall effectiveness is reduced. Few centers have continued to apply this procedure in carefully selected patients.

The current results for the Fontan are excellent, with hospital mortality ranging from 2% to 9%.^{154–158} The condition of survivors is generally good and most attain a functional status of New York Heart Association class I or II. The long-term results have been reported with a 93% to 97% 5-year survival and a 91% 10-year survival.^{156,157} Although long-term results are encouraging, late complications may be seen. Continued surveillance for arrhythmias, CHF, protein-losing enteropathy, and hepatic dysfunction remains important.

HYPOPLASTIC LEFT- HEART SYNDROME

Hypoplastic left-heart syndrome (HLHS) refers to a constellation of congenital cardiac anomalies characterized by marked hypoplasia or absence of the LV and severe hypoplasia of the ascending aorta. The systemic circulation is dependent on the right ventricle via a PDA and there is obligatory mixing of pulmonary and systemic venous blood in the right atrium. There is associated aortic valve stenosis or atresia, and mitral valve stenosis or atresia. The descending aorta is essentially a continuation of the ductus arteriosus, and the ascending aorta and aortic arch are a diminutive branch from this vessel. Initial management includes a prostaglandin infusion to maintain ductal patency and correction of metabolic acidosis. The patient may require intubation and ventilator adjustment to reduce supplemental oxygen and maintain a partial pressure of carbon dioxide (PCO₂) of about 40 mm Hg to avoid excessive pulmonary flow.

Treatment options for this problem include cardiac transplantation and staged reconstructive surgery. Transplantation for HLHS is generally performed with the same techniques that are standard for transplantation in older children and adults. However, it is necessary to have a generous amount of donor aortic arch that can be used to augment the hypoplastic recipient arch. Results of transplantation in neonates have been excellent in centers with extensive experience in this area, and a 2-year survival as high as 70% has been reported.¹⁵⁹ In the context of improving results for staged reconstruction, risks of immunosuppression, and limited donor availability, competing risk analysis favors staged repair, and most centers pursue this option as primary therapy for HLHS.¹⁶⁰ Transplantation is generally reserved for very high-risk patients, such as those with depressed right ventricular function or severe tricuspid regurgitation.

The first successful palliation of HLHS was reported by Norwood et al. on a series of infants operated on between 1979 and 1981.¹⁶¹ This procedure has been technically refined over the years, but three essential components remain: atrial septectomy, anastomosis of the proximal PA to the aorta with homograft augmentation of the aortic arch, and aortopulmonary shunt or right ventricle–PA conduit (Fig. 81-11). As described previously for the univentricular heart, subsequent reconstructive management of HLHS includes an interim hemi-Fontan procedure or bidirectional Glenn anastomosis at 4 to 6 months of age, followed by a Fontan procedure at about 18 to 24 months.

Universally fatal only two decades ago, tremendous strides have been made in improving the outcomes for patients with HLHS. Of the three stages, the highest-risk stage of the repair remains the Norwood operation. During the 1990s, the hospital survival for the Norwood procedure across the United States was approximately 40%.¹⁶² Currently, select centers have reported hospital survivals of 90% or greater.^{163–167} Reported survivals for the hemi-Fontan and Fontan procedures have also been excellent at 98% for both operations.^{155,157,168}

Chapter 82

Valvular Heart Disease and Cardiac Tumors

Tomislav Mihaljevic, Craig M. Jarrett, Husain T. AlQattan, Shehab Ahmad Redha AlAnsari, Haris Riaz, Marijan Koprivanac, and A. Marc Gillinov

Key Points

- 1 The most common cause of aortic stenosis (AS) is degenerative calcific disease, followed by congenital AS due to bicuspid valve anatomy.
- 2 Two-dimensional (2D) echocardiography with Doppler allows precise real-time analysis of valvular anatomy and function, and is the study of choice for the diagnosis and management of valvular lesions.
- 3 The current indication for cardiac catheterization in patients with valvular heart disease is limited to preoperative evaluation of coronary artery disease.
- 4 There is no effective medical therapy for patients with severe AS. Mechanical relief of the obstruction to blood flow is the only effective treatment.
- 5 The most common causes of aortic regurgitation (AR) include bicuspid valve disease, rheumatic fever, and endocarditis.
- 6 Mitral stenosis (MS) is almost exclusively caused by rheumatic fever.
- 7 The most common cause of mitral regurgitation is degenerative mitral valve disease. Other causes include rheumatic valve disease, endocarditis, certain drugs, and collagen vascular diseases.
- 8 The most common cardiac tumors are secondary tumors, which usually originate from the lung in men and from the breast in women.

VALVULAR HEART DISEASE

Valvular Anatomy

The basic structural framework of all heart valves is provided by the fibrous cardiac skeleton ([Fig. 82-1](#)). The skeleton is a collection of dense connective tissue in the shape of four interconnected rings in the plane between the atria and the ventricles. The interconnecting areas include the right fibrous trigone, which is between the aortic and tricuspid rings and contiguous with the membranous septum, and the left trigone and fibrous continuity, which are between the aortic and mitral rings and form the posterior wall of the left ventricular (LV) outflow tract. The cardiac skeleton maintains the integrity of the valve orifices and provides points of attachment for the valve leaflets. It also serves as a partition by electrically isolating the atria and ventricles except at the atrioventricular bundle, which passes through the right fibrous trigone near the septal leaflet of the tricuspid valve (TV).

The normal aortic valve (AV) consists of three semilunar leaflets or cusps projecting outward and upward into the lumen of the ascending aorta ([Fig. 82-2](#)). The space between the free edge of each leaflet and the points of attachment to the aorta comprise the sinuses of Valsalva. Since the coronary arteries arise from two of the three sinuses, the sinuses and the respective leaflets are named the right coronary, left coronary, and noncoronary (or posterior) sinuses and leaflets.

The properties of the AV ensure minimal obstruction to flow when open and minimal flow reversal when closed. Opening and closing of the valve are passive, as it functions only in response to pressure differences between the left ventricle and aorta during the cardiac cycle. The pressure generated from ventricular contraction forces the valve open, and the subsequent recoil of blood from the aorta fills the sinuses of Valsalva and forces the leaflets closed.

There are two structures in close proximity to the AV and, therefore, susceptible to injury during AV surgery ([Fig. 82-2](#)). First, the anterior leaflet of the mitral valve (MV) is positioned under the commissure between the left and noncoronary leaflets. Second, the left bundle of His is positioned under the commissure between the right and noncoronary leaflets.

In contrast to the simplistic anatomy and passive opening and closing mechanism of the AV, the anatomy and active valve mechanism of the MV are more complex. Indeed, proper functioning of the MV depends on the organized interaction of all components of the MV apparatus, which consists of the leaflets, annulus, LV papillary muscles, and chordae tendineae.

The normal MV consists of two leaflets: the anterior and posterior leaflets. The anterior leaflet is semicircular in shape, extends from the anteromedial aspect of the mitral annulus, and encompasses approximately one-third of the annular circumference. The posterior leaflet is rectangular in shape, extends from the posterolateral aspect of the mitral annulus, and encompasses approximately two-thirds of the annular circumference. The leaflets are separated from one another at the annulus by the posteromedial and anterolateral commissures. Both leaflets are divided by clefts into three scallops, named laterally to medially A1, A2, and A3, and P1, P2, and P3, and together comprise an average cross-sectional area of 5 to 11 cm².

The mitral annulus is formed anteriorly by the confluence of the right, left, and intervalvular fibrous trigones and posteriorly by a fibrous band. Since the anterior aspect of the mitral annulus is composed of the fibrous trigones, it has limited flexibility. Conversely, the posterior aspect of the annulus, which is not surrounded by any rigid structures, has more flexibility. This increased flexibility of the posterior aspect relative to the anterior aspect has important implications during the cardiac cycle. In systole the mitral annulus contracts (primarily the posterior aspect) and adopts an elliptical shape (shortening occurs perpendicular to the line of leaflet coaptation), and in diastole it relaxes and adopts a circular shape.^{1,2} This dynamic motion of the annulus provides increased leaflet coaptation during systole and increased orifice area during diastole.

Figure 82-1. Schematic diagram of the fibrous cardiac skeleton.

Two papillary muscles arise directly from the ventricular wall: the anterolateral and posteromedial papillary muscles. Importantly, the anterolateral papillary muscle usually is supplied by two coronary arteries, the left anterior descending artery and branches of the circumflex artery. On the other hand, the posteromedial papillary muscle is usually supplied by a single coronary artery, either from the right coronary or the circumflex artery, which makes it twice as likely to rupture from ischemia and infarction as the anterolateral papillary muscle. The papillary muscles play an important role in the proper function of the MV. MV closure and appropriate leaflet coaptation are permitted by end-diastolic and early systolic lengthening of the papillary muscles.³

Chordae tendineae attach the leaflets to the papillary muscles or directly to the ventricular wall and can be categorized based on the attachments. Primary chordae attach to the leaflets at the free edge to ensure proper coaptation without prolapse or flail. The secondary chordae attach along the line of coaptation and are more prominent on the anterior leaflet. Tertiary chordae arise directly from the ventricle or trabeculae carneae and are only present on the posterior leaflet. Finally, commissural chordae attach to both leaflets and arise from either papillary muscle.

The structures in close proximity to the MV and, therefore, susceptible to injury during MV surgery

include the AV, the atrioventricular node, and the circumflex coronary artery (Fig. 82-3).

Figure 82-2. Schematic diagram of the relationship of the aortic valve to the underlying structures.

AORTIC STENOSIS

Prevalence and Etiology

1 Aortic stenosis (AS) is the most prevalent valvular heart disease in developed countries. The most common cause of AS is degenerative calcific disease, followed by congenital AS due to bicuspid valve anatomy. Rheumatic AS is becoming exceedingly uncommon in developed countries due to efficient prevention of rheumatic heart disease.

Figure 82-3. Schematic diagram of the relationship of the mitral valve to the underlying structures.

Degenerative Calcific Aortic Stenosis

The most frequent cause of AS is degenerative calcification of the AV. The prevalence of degenerative AS in persons older than 65 years, which is the most commonly affected age group, is 2%.⁴ The degenerative process that leads to stiffening of the aortic leaflets is the result of proliferative and inflammatory changes with lipid accumulation and infiltration of macrophages and T lymphocytes.⁴⁻⁹ Fibrosis and calcification initially affect the base of the leaflets, but ultimately progress to immobilization of the leaflets due to large calcific deposits that can extend deep into the annulus. These deposits may also extend onto the ventricular surface of the anterior leaflet of the MV, as well as into the wall of the ascending aorta. The risk factors for the development of calcific AS are similar to those for atherosclerosis and include elevated serum levels of low-density lipoprotein (LDL) cholesterol, diabetes, smoking, and hypertension.^{10,11}

Bicuspid Aortic Stenosis

Calcification of bicuspid AVs, which are present in approximately 2% of the general population,

represents the most common form of congenital AS. In patients with bicuspid AVs, the left and right coronary cusps are usually fused, while the noncoronary cusp is freestanding. Gradual calcification of the bicuspid valve results in AS with typical onset of symptoms in the fifth or sixth decade of life, in contrast to degenerative AS, which causes symptoms in elderly individuals. Bicuspid AS is frequently associated with degenerative changes in the wall of the ascending aorta with resultant dilation or aneurysm formation.

Rheumatic Aortic Stenosis

Introduction of effective antibiotic therapy has resulted in a decline in the prevalence of rheumatic fever and rheumatic valve disease. Rheumatic AS is caused by inflammation and thickening of the AV leaflets, producing a mixture of AS and regurgitation. Rheumatic AS is rarely an isolated disease, and usually occurs in conjunction with MV stenosis.¹²

Pathophysiology

Regardless of the etiology of AS, the pathophysiologic consequences are similar. Narrowing of the AV to one-quarter of its normal area of 3 to 4 cm² produces a significant pressure gradient between the left ventricle and aorta. There is a resultant increase in LV workload and compensatory LV hypertrophy.

Even though this hypertrophy is an appropriate response to the increased afterload, there are numerous harmful effects. First, the increased wall thickness makes the ventricle stiff and less compliant. This leads to diastolic dysfunction and increased wall tension. In addition to diastolic dysfunction, systolic dysfunction, typically occurring later in the course of the disease, can develop from chronic ischemia. All of the following contribute to increased myocardial oxygen demand: increased LV muscle mass, increased wall tension, increased systolic ventricular pressure, and increased systolic ejection time. There is also decreased coronary artery perfusion, which occurs during diastole, due to increased wall tension, increased diastolic ventricular pressure, and decreased diastolic aortic pressure.^{13,14} The subsequent ischemia of the subendocardium due to increased oxygen demand and decreased perfusion leads to cell death and fibrosis. Chronically, this ischemia results in systolic dysfunction.

Diagnosis

Symptoms

The most common symptoms of AS are angina pectoris, syncope, and heart failure.¹⁵ Angina pectoris occurs in 30% to 50% of patients with severe AS. It is a reflection of myocardial ischemia caused by increased metabolic demands and decreased coronary perfusion. Coronary artery disease, which affects more than 70% of elderly patients with degenerative AV disease, causes further deterioration of myocardial perfusion and lowers the threshold for angina.

Syncope is most commonly due to reduced cerebral perfusion that occurs during exertion. Reduced cerebral perfusion is a result of decreased mean arterial pressure from peripheral vasodilation in the presence of a fixed cardiac output. Approximately 15% of patients present with syncope and only 50% of these survive for 3 years.

Congestive heart failure in patients with severe AS is typically a sign of advanced and longstanding disease. It is marked by shortness of breath and dyspnea with exertion, and results from ongoing LV outflow obstruction. Heart failure is a consequence of the aforementioned diastolic and systolic dysfunction from decreased compliance and ischemia, respectively. In addition, as the left ventricle becomes less compliant, atrial systole becomes more important for maintaining cardiac output and the onset of atrial fibrillation may result in worsening of congestive heart failure.

Some patients with severe AS may develop serious gastrointestinal bleeding secondary to angiodysplasias, occurring predominantly in the right colon, and also in the small bowel and stomach. These result from shear stress-induced platelet aggregation with reduction in high-molecular-weight multimers of von Willebrand factor.

Signs

Signs of AS include a loud systolic ejection murmur that radiates to the neck and is often accompanied by a thrill. “Pulsus parvus et tardus” describes a weak and prolonged arterial pulse characteristic of advanced AS. The weak pulse is a reflection of a narrowed pulse pressure, while the slow rise in pulse reflects a prolonged ejection of blood volume through a stenotic valve.¹⁶

Electrocardiogram and Imaging

2 The electrocardiogram typically shows signs of LV hypertrophy, which is found in the majority of patients with AS. Echocardiography represents the “gold standard” modality for the diagnosis of AS. Two-dimensional (2D) echocardiography with Doppler allows precise real-time analysis of ventricular and valvular anatomy and function. The most important objective of echocardiography is correct assessment of the severity of AS using Doppler echocardiography to calculate jet velocity, mean transvalvular pressure gradient, and valve orifice area (Table 82-1). It is also used to assess valve thickening and calcification, as well as reduced leaflet motion. Distinction between bicuspid and TVs is often possible, particularly when the amount of calcification is small.

DIAGNOSIS

Table 82-1 Classification of Aortic Stenosis Severity

Indicator	Mild	Moderate	Severe
Jet velocity (m/s)	<3.0	3.0–4.0	>4.0
Mean gradient (mm Hg)	<25	25–40	>40
Valve area (cm ²)	>1.5	1.0–1.5	<1.0
Valve area index (cm ² /m ²)			<0.6

Adapted from Bonow RO, Carabello BA, Chatterjee K, et al. 2008 focused update incorporated into the ACC/AHA 2006 guidelines for the management of patients with valvular heart disease. *J Am Coll Cardiol* 2008;52(13):e1–e142.

Two-dimensional echocardiography is also invaluable in detecting associated MV disease and in assessing LV hypertrophy, systolic function, and diastolic performance. Ejection fraction is used to measure LV systolic function. However, a severe decrease in ejection fraction can falsely lower estimates of severity of AS due to low-pressure gradients. Stress echocardiography with dobutamine administration may be required to properly assess the severity of valvular disease and to distinguish it from primary contractile dysfunction with lack of contractile reserve.¹⁷

3 Cardiac catheterization with direct measurement of the pressure gradients across the AV to calculate the severity of stenosis has been replaced by less invasive echocardiography. The current indication for cardiac catheterization is limited to preoperative evaluation of coronary artery disease.

Natural History

The natural history of AS is marked by a prolonged latent period with few symptoms and minimal morbidity. Even patients with moderately severe AS have a slow decrease in AV area, generally by approximately 0.1 cm² per year.^{18,19} The natural history of severe AS correlates well with the onset and severity of symptoms. Life expectancy of patients with severe, untreated AS and angina is approximately 5 years. Patients presenting with syncope have life expectancies of 3 years. Presence of congestive heart failure in patients with severe, untreated AS is associated with a worse prognosis, with the time of death occurring less than 2 years from the onset of symptoms (Fig. 82-4).²⁰

Figure 82-4. Natural history of aortic stenosis without operative treatment. Onset of symptoms identifies patients at high risk of death over the next 2 to 5 years.

Figure 82-5. St. Jude Medical Regent Valve.

Treatment

4 There is no effective medical therapy for patients with severe AS. Diuretics and digitalis may improve the symptoms of congestive heart failure. Mechanical relief of AS is accomplished by surgical AV replacement (AVR), percutaneous AVR, or percutaneous balloon aortic valvotomy (PBAV).

Surgical Aortic Valve Replacement

The primary indication for surgery is the presence of symptoms in patients with severe AS. AVR is also indicated in patients with severe AS and reduced LV function and in patients with moderate to severe AS who also require coronary, other valve, or aortic surgery.¹⁷ Recent studies suggest that AVR may also be beneficial in patients with asymptomatic severe AS and severe LV hypertrophy.²¹

Choice of valve prosthesis for AVR is primarily influenced by the patient's age. Mechanical prostheses are made of carbon, require lifelong anticoagulation, and are very durable (Fig. 82-5). Mechanical prostheses are therefore indicated in patients younger than 65 years old. Stented biologic prostheses are most commonly made of bovine pericardium or porcine valve leaflets, do not require anticoagulation, and have a limited durability of approximately 15 years (Fig. 82-6). Biologic prostheses are used in elderly patients (older than 65 years) and in younger patients in whom long-term anticoagulation with warfarin is contraindicated (bleeding diathesis, peptic ulcer disease, etc.).

Percutaneous and Transapical Aortic Valve Replacement

Percutaneous AVR is an emerging therapy for patients previously deemed inoperable due to prohibitive operative risk. This is a novel treatment utilizing a bioprosthesis sutured to a balloon or self-expandable stainless steel or nitinol stent (Fig. 82-7). The prosthesis is introduced through the femoral artery retrogradely into the aorta and placed at the midpart of the native stenotic AV. The radial forces of the stent push the native AV aside to increase the valve orifice area. The prospective trial (Placement of Aortic Transcatheter valves: PARTNER) randomized "high-risk" patients (operative mortality >15%) to either transfemoral AVR (TF-AVR) or conventional AVR.²² Thirty-day mortality was doubled in the conventional group, but at 1 year, survival was similar. In the "inoperable" subset, TF-AVR was shown to be significantly superior to optimal medical therapy with improvement in NYHA scores to 1–2 and a 20% improvement in mortality at 5-year follow-up. Hemodynamic benefits and valve integrity also persisted at 5 years.²³ In patients with severe peripheral vascular disease, the retrograde arterial approach cannot be used. In these patients, similar prostheses can be inserted directly into the beating heart through the LV apex (transapical approach). This approach has been shown to have a lower rate of vascular complications, postoperative heart block necessitating permanent pacemaker implantation and paravalvular regurgitation as compared to the TF-AVR with similar 1-year survival.^{24–26} In conclusion, appropriately selected high-risk or inoperable patients can benefit significantly from TF-AVR in both survival and functional status, and in those where femoral access is not an option, the transapical technique is warranted.

Figure 82-6. St. Jude Medical Epic Valve.

Percutaneous Balloon Aortic Valvotomy

PBAV is a procedure in which a balloon is placed across a stenotic AV and inflated in order to decrease the degree of valve narrowing. This procedure is a valuable tool for treatment of AS in children and young adults. Rapid development of restenosis and clinical deterioration limits its application in the treatment of adults to those with severe AS who are not candidates for conventional surgical or transcatheter AVR.

AORTIC REGURGITATION

Prevalence and Etiology

5 AR results from the improper coaptation of the AV leaflets due to either intrinsic leaflet abnormalities or aortic root distortion. The most common causes of AR include bicuspid valve disease, rheumatic fever, and endocarditis. Regurgitant bicuspid AVs are often partly calcified, which results in limited opening and closing of the valve and a mixture of AR and AS. Rheumatic fever causes inflammation and fibrosis of the leaflets, while endocarditis causes destruction of leaflets. In addition, AR can occur as a secondary phenomenon of aortic root enlargement due to Marfan syndrome, anuloaortic ectasia, or aortic dissection. Most of these causes produce chronic AR with a slow increase in LV size. Some lesions, in particular acute aortic dissection and endocarditis, cause acute AR with a sudden decrease in cardiac output.

Pathophysiology

In patients with AR, inappropriate coaptation of the aortic leaflets causes diastolic reflux of blood from the aorta into the LV with a consequent increase in LV end-diastolic volume and pressure. In chronic AR, compensatory mechanisms of the LV result in dilation and hypertrophy. LV hypertrophy and dilation ultimately result in a decrease in LV function and heart failure.

Diagnosis

Symptoms

Chronic AR is usually well tolerated and patients with even severe AR often remain asymptomatic for years. Initial symptoms of severe AR include fatigue, shortness of breath, and dyspnea on exertion. Advanced AR is marked by the onset of congestive heart failure, syncope, and angina. Acute onset of severe AR, such as in cases of aortic dissection or endocarditis-induced valve destruction, causes a sudden increase in LV end-diastolic volume and pressure with subsequent cardiogenic shock and pulmonary edema.

Signs

Lateral displacement of the point of maximum impulse is seen in chronic AR due to LV dilation and hypertrophy. The classic auscultatory findings of AR are best heard at the right sternal border of the second intercostal space and include a high-pitched, blowing holodiastolic decrescendo murmur; an S_3 heart sound; and a systolic ejection murmur.

DIAGNOSIS

Table 82-2 Classification of Aortic Regurgitation Severity

Indicator	Mild	Moderate	Severe
Angiographic grade	1+	2+	3–4+
Jet width	<25% LVOT	25–65% LVOT	>65% LVOT
Regurgitant volume (mL/beat)	<30	30–59	≥60
Regurgitant fraction (%)	<30	30–49	≥50
Regurgitant orifice area (cm ²)	<0.10	0.10–0.29	≥0.30

LVOT, left ventricular outflow tract.
Adapted from Bonow RO, Carabello BA, Chatterjee K, et al. 2008 focused update incorporated into the ACC/AHA 2006 guidelines for the management of patients with valvular heart disease. *J Am Coll Cardiol* 2008;52(13):e1–e142.

Additionally, the widened pulse pressure leads to a number of interesting findings, such as bounding pulses (water-hammer pulse), Quincke pulse (pulse in fingernail bed), De Musset sign (rhythmic bobbing of the head), Duroziez sign (systolic and diastolic murmurs heard over the femoral artery when it is gradually compressed), and Müller sign (pulsations of the uvula).¹⁶

Imaging

Echocardiography represents the diagnostic “gold standard” for patients with AR. It allows assessment of the valvular and aortic anatomy, the severity of regurgitation, and the size and function of the left ventricle. Assessment of the severity of AR is determined by color Doppler jet width, regurgitant volume, regurgitant fraction, and regurgitant orifice area (Table 82-2). The role of coronary angiography is reduced to the preoperative diagnosis of coronary artery disease.

Natural History

The natural history of AR is strongly dependent on the presence of symptoms and LV dysfunction at the time of presentation. Asymptomatic patients with normal LV function develop symptoms and/or LV dysfunction at 6% per year. Asymptomatic patients with LV dysfunction at presentation develop cardiac symptoms at 25% per year. Finally, the mortality rate of symptomatic patients is 10% per year.¹⁷

Treatment

Management of patients with AR depends on the severity of symptoms and the size and function of the left ventricle. Asymptomatic patients with chronic severe AR and preserved LV size and function are treated with vasodilator medical therapy, which reduces afterload and improves forward flow.

Surgery is indicated in symptomatic patients with chronic severe AR and in asymptomatic patients with severe AR and evidence of LV dilation (end-systolic LV diameter >55 mm) or dysfunction (ejection fraction <50%). Additionally, acute severe AR with consequent pulmonary edema and shock caused by endocarditis or aortic dissection is a surgical emergency.

AVR should be performed before irreversible changes in LV function occur. Mechanical valves are indicated for patients younger than 65 years of age. Stented bioprostheses are used for AVR in patients older than 65 and in younger patients with contraindications to long-term anticoagulation. AV repair can be performed in patients with severe AR caused by bicuspid valve disease or connective tissue

disorders. Traditionally, patients with proximal aortic root pathology, including dissection and aneurysms with secondary AR underwent aortic root replacement with a mechanical valve. This was done regardless whether or not their native valve was diseased. The valve sparing root replacement (David procedure) has been shown to have similar morbidity and mortality with minimal risk of thromboembolism or endocarditis. Additionally, it precludes the need for anticoagulation and has an acceptably low reoperation rate. This makes it ideal for young patients, especially those with connective tissue disorders.^{27–30}

MITRAL STENOSIS

Prevalence and Etiology

6 Mitral stenosis (MS) is predominantly caused by rheumatic fever. The steady rate of decline of rheumatic fever in developed countries has resulted in a similar decline in the prevalence of MS. Other far less common causes of MS include severe annular and leaflet calcification, congenital malformations, malignant carcinoid, left atrial myxoma, left atrial thrombus, and endocarditis. A definitive history of rheumatic fever can only be obtained in 50% to 60% of cases and women are affected more often than men by a 2:1 ratio.^{31,32} Rheumatic fever commonly occurs in childhood or adolescence and can lead to a postinfective pancarditis, affecting to various degrees the valves, endocardium, myocardium, and pericardium. In MS due to rheumatic fever, there is leaflet thickening and calcification, chordal shortening and fusion, and commissural fusion, which all lead to a smaller, funnel-shaped mitral orifice. This deformation can also prevent complete closure of the valve, which is evidenced by concomitant regurgitation in about half of patients with MS.

Pathophysiology

The cross-sectional area of the normal MV is 4 to 5 cm². Normally, there is a trivial diastolic pressure gradient present to move blood across the MV from the left atrium into the left ventricle. An increasing gradient is required as the MV becomes more narrowed, and a significant transvalvular gradient first develops when there is reduction of the mitral orifice to less than 2.5 cm², which represents mild MS. The increased atrial pressure leads to left atrial enlargement and the pressure is subsequently transmitted retrograde into the pulmonary veins, capillaries, and arteries. The determinants of the transvalvular gradient, and therefore the determinants of the left atrial pressure, are atrial contractility, cardiac output, and heart rate. Consequently, the gradient and atrial pressure are increased if atrial kick is lost (decreased atrial contractility), flow rate across the valve increases (increased cardiac output), or transit time across the valve is shortened (increased heart rate).

Diagnosis

Symptoms

Symptoms of left-sided heart failure, such as dyspnea, orthopnea, and paroxysmal nocturnal dyspnea, are the primary indicators of MS and are typically triggered by exertion, stress, infection, pregnancy, or the abrupt onset of atrial fibrillation. The increased heart rate and cardiac output that can occur under these circumstances, and the mechanical obstruction inherent to MS, lead to an increased transvalvular gradient and left atrial pressure. The ensuing pulmonary congestion results in dyspnea. Likewise, the loss of atrial kick with atrial fibrillation increases the gradient and atrial pressure. Patients with atrial fibrillation may also present with palpitations or systemic embolization.

Patients infrequently present with hoarseness, dysphagia, hemoptysis, and symptoms of right-sided heart failure. Hoarseness and dysphagia may result if left atrial enlargement is sufficient to compress surrounding structures. Hemoptysis may occur from significant pulmonary venous hypertension. Symptoms of right-sided heart failure arise when right ventricular function is impaired due to an increased afterload from the stenotic MV and secondary pulmonary hypertension. Still, other patients may present without symptoms but have an abnormal physical examination.

Signs

The left ventricle is typically not enlarged; thus, the point of maximum impulse is not displaced. The typical auscultatory findings of MS are best heard at the apex and include a low-pitched, rumbling middiastolic murmur; an accentuated first heart sound; and an opening snap. These findings may be

absent with a heavily calcified immobile valve, severe pulmonary hypertension, or low cardiac output. Physical findings of pulmonary hypertension, such as a loud pulmonic component of the second heart sound (P₂), a right ventricular heave, distended neck veins, hepatomegaly, ascites, and peripheral edema, can also be observed with MS.¹⁶

Imaging

Echocardiography is the principal tool used in the diagnosis of MS. It is used to assess the morphologic characteristics of the valve apparatus, which include leaflet mobility, flexibility, and thickness; presence of calcifications and subvalvular fusion; and appearance of the commissures. Additionally, Doppler echocardiography is utilized to determine the hemodynamic severity by measurement of the mean transvalvular pressure gradient, pulmonary artery systolic pressure, and valve area (Table 82-3). This morphology and severity information is fundamental in determining the timing and type of intervention to be used.¹⁷

The enlarged left atrium gives rise to characteristic findings on the chest radiograph, which includes displacement of the left main-stem bronchus superiorly and displacement of the esophagus posteriorly. Additionally, calcification of the mitral leaflets and enlarged pulmonary arteries with cephalization of pulmonary blood flow can be seen.

Similar to the diagnosis of other valvular heart disease, cardiac catheterization with direct pressure measurement has largely been replaced by echocardiography.

DIAGNOSIS

Table 82-3 Classification of Mitral Stenosis Severity

Indicator	Mild	Moderate	Severe
Mean gradient (mm Hg)	<5	5–10	>10
Pulmonary artery systolic pressure (mm Hg)	<30	30–50	>50
Valve area (cm ²)	>1.5	1.0–1.5	<1.0

Adapted from Bonow RO, Carabello BA, Chatterjee K, et al. 2008 focused update incorporated into the ACC/AHA 2006 guidelines for the management of patients with valvular heart disease. *J Am Coll Cardiol* 2008;52(13):e1–e142.

Natural History

The natural history of MS is that of a continuous decline usually consisting of a slow, stable course followed by a progressive acceleration. The latent period from rheumatic fever to the onset of symptoms is typically 20 to 40 years, with another decade before symptoms become disabling. Depending on the symptoms at presentation, the overall 10-year survival of untreated patients presenting with MS is 50% to 60%. Once disabling symptoms occur, the 10-year survival is a bleak 0% to 15%.^{31–34} Mortality in untreated patients is due to pulmonary and systemic congestion, systemic embolism, pulmonary embolism, and infection.^{33,35}

Treatment

For the asymptomatic patient with mild MS in sinus rhythm, prophylaxis against rheumatic fever is the only therapy indicated. A yearly history, physical examination, chest radiograph, and electrocardiogram should be obtained; serial echocardiograms are only warranted in patients with severe MS or when there is a change in symptoms.¹⁷

Mechanical relief is considered in symptomatic patients with moderate to severe MS. In symptomatic patients with mild MS, further exercise testing or dobutamine stress testing is useful to determine whether or not mechanical relief is warranted. Patients with a significant elevation of mean transmitral gradient (> 15 mm Hg), pulmonary artery systolic pressure (> 60 mm Hg), or pulmonary artery wedge pressure (> 25 mm Hg) during provocative testing have hemodynamically significant MS and should be considered for mechanical relief.¹⁷ The options for mechanical relief of MS include percutaneous balloon mitral valvotomy, open mitral commissurotomy (OMC), and MV replacement.

Percutaneous Balloon Mitral Valvotomy

Percutaneous balloon mitral valvuloplasty (PBMV) was initially introduced in 1984 marking a leap in transcatheter-based therapies for valvular heart disease. Most commonly, the catheter is introduced into

the right atrium via a transseptal approach and inflated across the diseased valve.³⁶ This has become the standard of care for select MS patients.¹⁷ Scoring systems have been developed to aid in patient selection. Leaflet thickness, pliability, degree of calcification of the valves and the subvalvular apparatus are central in these scoring systems with lower scores (e.g., <8 in the Wilkins score) correlating with improved outcomes.³⁷ Contraindications include the presence of a left atrial thrombus, moderate to severe MR, heavy annular or leaflet calcification, and severe subvalvular distortion.

Procedural mortality of PBMV is 1% to 2% in large series. Rare risks of the procedure include MR, iatrogenic creation of an atrial septal defect, perforation of the left ventricle, embolic events, and myocardial infarction.^{38–42}

Success of PBMV can be measured by the increase in mitral valve area (MVA), restenosis at long-term follow-up and event-free survival (death, repeat procedure or surgery, NYHA III or IV). Overall, significant (MVA ≥ 1.5 cm²) increase in MVA are obtained in over 80% of patients⁴³ with freedom from restenosis and event-free survival at 10 years at 70% and 80%, respectively.^{44,45}

Open Mitral Commissurotomy

OMC permits direct inspection of the MV apparatus and allows debridement of calcium deposits, division of the commissures, and splitting of fused chordae tendineae under direct vision. Additionally, the left atrial appendage can be surgically oversewn from within the left atrium, reducing the risk of postoperative embolization. The contraindications to OMC are similar to those of PBMV.

The operative mortality of OMC is less than 2%,^{46,47} and complication rates are similar to those of PBMV.^{48,49} Short- and long-term hemodynamic results and symptomatic results are similar between PBMV and OMC in younger patients with less severe valve pathology (lower Wilkins scores).⁴⁸ More favorable results are seen with OMC in older patients with subvalvular fusion, leaflet calcification, and less valve flexibility (higher Wilkins scores).⁴⁹

Mitral Valve Replacement

MV replacement is necessary in symptomatic patients with moderate to severe MS when there is a significant amount of calcification or subvalvular fusion, since PBMV and OMC are less likely to be successful. MV replacement is also necessary in symptomatic patients with moderate to severe MS and concomitant moderate to severe MR.¹⁷ The choice of valve prosthesis for MV replacement is determined in a similar manner as choosing the prosthesis for AVR. Biologic prostheses are used in the elderly and those in whom long-term warfarin is contraindicated. Regardless of the prosthesis used, it is well established that preservation of the papillary muscle attachments to the annulus plays an important role in the maintenance of LV function.^{50–54} The operative mortality of MV replacement is 5% to 6% and freedom from reoperation at 15 years is 50% to 75%.⁵⁵

MITRAL REGURGITATION

Prevalence and Etiology

8 Since competency of the MV is dependent on the entire MV apparatus, dysfunction of any one of the components can lead to mitral regurgitation (MR). The most common overall cause of MR is degenerative MV disease. Other causes of MR include rheumatic valve disease, endocarditis, certain drugs, and collagen vascular disease. In some cases, functional MR develops as a result of dilation of the LV from cardiomyopathy or severe ischemic heart disease. Finally, rupture of a papillary muscle from myocardial infarction or endocarditis, or rupture of a chord can lead to the onset of acute, severe MR.

Pathophysiology

MR is caused by deficient coaptation of the MV leaflets, which results in blood flow from the left ventricle into the left atrium during systole. Regardless of etiology, the pathophysiology of chronic MR is similar. MR results in gradual enlargement of the left atrium as a result of volume overload. Decrease in the functional stroke volume causes an increase in LV size with a subsequent decrease in LV function.

On the other hand, the pathologic process that takes place in acute MR is quite different. Sudden volume overload results in an increase in LV preload and a decrease in forward stroke volume, since compensatory LV eccentric hypertrophy has not had time to develop. Similarly, acute volume overload of the left atrium results in an increase in left atrial pressure and pulmonary congestion.

Diagnosis

Symptoms

Symptoms of chronic MR include fatigue, dyspnea on exertion, and shortness of breath. More advanced stages of disease are characterized by the development of heart failure. Acute, severe MR is characterized by acute pulmonary edema and cardiogenic shock.

Signs

The point of maximum impulse is typically laterally displaced. The classic auscultatory findings of MR are best heard at the apex and include a high-pitched, blowing, holosystolic murmur radiating to the axilla; a diminished S₁; and an S₃.

Imaging

Echocardiography is used to assess the severity of MR, morphology of the MV, and size and function of the LV and atrium. Assessment of the severity of MR is determined by the jet area/left atrial area, regurgitant volume, regurgitant fraction, and regurgitant orifice area (Table 82-4). Additionally, magnetic resonance imaging (MRI) allows accurate measurements of the severity of regurgitation and quantification of regurgitant volumes, along with assessment of LV size and function.

Natural History

Patients with mild to moderate MR usually remain asymptomatic with little or no hemodynamic compromise for many years. In patients with severe MR caused by flail leaflets, mortality is 6% to 7% per year, and 90% of patients die or require an MV operation within 10 years.⁵⁶

Treatment

Given most recent guidelines, surgery should be performed early, before signs of LV function deterioration, and even asymptomatic patients with severe MR should be offered surgery if there is a high probability of successful repair and low mortality risk.^{57,58} MV repair is preferred surgical therapy for most patients with MR, since it preserves the native valve and avoids the need for anticoagulation, which is required in the majority of patients who undergo valve replacement.⁵⁹ Preservation of the MV and chordae preserves LV function and improves survival. Success rates of MV repair depend on the etiology of regurgitation. Durable MV repair can be accomplished in more than 90% of patients with degenerative MV disease. Standard techniques for MV repair include resection of the prolapsed portion of the MV leaflet, leaflet reconstruction, and insertion of an annuloplasty ring (Fig. 82-8).

DIAGNOSIS

Table 82-4 Classification of Mitral Regurgitation Severity

Indicator	Mild	Moderate	Severe
Angiographic grade	1+	2+	3–4+
Jet size			Wall-impinging jet of any size
Jet area/left atrial area (%)	<20	20–40	>40
Regurgitant volume (mL/beat)	<30	30–59	≥60
Regurgitant fraction (%)	<30	30–49	≥50
Regurgitant orifice area (cm ²)	<0.20	0.20–0.39	≥0.40

Adapted from Bonow RO, Carabello BA, Chatterjee K, et al. 2008 focused update incorporated into the ACC/AHA 2006 guidelines for the management of patients with valvular heart disease. *J Am Coll Cardiol* 2008;52(13):e1–e142.

Figure 82-8. Schematic diagram of posterior mitral valve repair and insertion of annuloplasty ring.

Mortality of isolated MV repair is less than 1%, with greater than 90% freedom from reoperation at 10 years. Functional MR is usually repaired with the use of an undersized annuloplasty ring to reduce the diameter of the mitral annulus and restore valve competency. MV repair is also the preferred surgical therapy in patients with MV endocarditis. Resection of all infected valve tissue is the mainstay of valvular reconstruction in patients with endocarditis. This is followed by leaflet reconstruction, commonly with the use of an autologous pericardial patch and an annuloplasty (Fig. 82-9).

MV repair is indicated for patients in whom adequate MV repair cannot be accomplished. Mechanical valve replacements are indicated in patients younger than 65 years of age and stented bioprostheses are indicated in the elderly.

Isolated MV repair and replacement are traditionally performed through a full sternotomy. Minimally invasive approaches, which include partial upper and lower sternotomy and right mini anterolateral thoracotomy, decrease the degree of surgical trauma and blood loss and allow faster recovery with less postoperative pain, sternal wound complications, and better cosmetic result.⁶⁰⁻⁶² Robotically assisted MV repair, which is performed through small port-like incisions, is the least invasive surgical approach that eliminates the need for sternotomy or thoracotomy, and as such provides faster postoperative recovery in hospital as well as after discharge (Fig. 82-10).⁶³⁻⁶⁶

Figure 82-9. Schematic diagram of mitral valve repair with autologous pericardial patch and insertion of an annuloplasty ring.

Figure 82-10. Surgical approaches to the mitral valve. **A:** Full sternotomy. **B:** Partial sternotomy. **C:** Limited right anterolateral mini-thoracotomy. **D:** Robotically assisted.

In patients with severe MR who are determined to be at prohibitive risk for surgery given existing comorbidities alternative treatment option is percutaneous MV repair. MitraClip system is a percutaneously delivered device that offers similar mortality and symptomatic improvement. However, due to higher rate of MR requiring repeat procedures, and less improvement in LV dimensions as compared to surgery, the latter remains the standard of care for treatment of MR among eligible patients. ⁶⁷

TRICUSPID VALVE DISEASE

TV disease is less common than AV and MV disease. Tricuspid regurgitation (TR), the most common form of TV dysfunction, can occur with anatomically normal or abnormal valves. Functional TR is caused by right ventricular dilation and consequent leaflet malcoaptation in an otherwise anatomically normal valve. Right ventricular enlargement occurs in patients with pulmonary hypertension, most commonly caused by longstanding MV dysfunction. TV endocarditis most commonly occurs in intravenous drug users and causes TR by destruction of the leaflets.

Echocardiography is used to assess the degree of TR, anatomy of the TV, right ventricular function, and pulmonary pressures.

Mild to moderate degrees of TR often resolve spontaneously once the MV disease causing the pulmonary hypertension is corrected. Severe functional TR is corrected by reduction in the diameter of the tricuspid annulus, most commonly using an annuloplasty ring. Severe endocarditis requires complete resection of infected valve tissue, followed by TV replacement with a bioprosthesis. In active drug users, insertion of a valve prosthesis may be delayed by several months to decrease the risk of recurrent endocarditis.

Valve Prostheses

Development of valve prostheses has transformed the treatment of valvular heart disease. Numerous types of prostheses are currently available for clinical use, and they differ in design, biocompatibility, and hemodynamic characteristics. They are broadly classified into mechanical and bioprosthetic.

Contemporary mechanical valves are bileaflet valves composed of carbon material that is mounted on a sewing ring (Fig. 82-5). Mechanical valve prostheses are durable and have excellent hemodynamic performance. Patients with mechanical prostheses require lifelong anticoagulation with warfarin, which results in a 1% to 3% risk of bleeding per year. These characteristics make mechanical valves the prosthesis of choice for younger patients with no contraindications to long-term anticoagulation.¹⁷

Biologic prostheses are composed of valve leaflets created from bovine pericardium or porcine valve leaflets mounted on a sewing ring (Fig. 82-6). Biologic prostheses have slightly inferior hemodynamic characteristics when compared with mechanical prostheses and a limited durability of 10 to 15 years. However, bioprostheses are not thrombogenic and therefore do not require anticoagulation. Bioprostheses are generally indicated in older individuals and younger patients who have contraindications to long-term anticoagulation.

There has been an increased use of bioprostheses in younger individuals due to recent improvements in design of the prostheses, expected increases in valve durability, and decreased risk of reoperations.

Aortic homografts are cryopreserved allografts that are composed of AVs and ascending aortas. Homografts are not thrombogenic, have excellent hemodynamic characteristics, and have high resistance to infection. Homografts are indicated in patients with AV endocarditis. Their use for primary AVR is limited due to the complexity of the operation and limited durability (10 years).

CARDIAC TUMORS

Cardiac tumors can be located in the epicardium, myocardium, endocardium, or any combination of the three. In general, tumors that involve the parietal pericardium are not classified as cardiac tumors.

8 Tumors of the heart are classified as either primary or secondary. Primary tumors arise in the heart and are either benign or malignant. Secondary tumors are metastases from primary tumors arising elsewhere and hence are always malignant. Primary tumors are rare, with an autopsy incidence of less than 0.1%.⁶⁸ Secondary tumors are observed more commonly, with a postmortem incidence of about 1%.⁶⁹

Cardiac tumors present with variable symptoms. Symptoms are frequently determined by the intracardiac location of the tumor. Intracavitary tumors can obstruct blood flow, causing signs and symptoms that mimic those of valvular heart disease. Intracavitary tumors can also cause embolic events, resulting in symptoms related to the site of embolization. Intramyocardial tumors can trigger cardiac rhythm disturbances, including sudden death.⁷⁰ Cardiac tumors can also cause systemic symptoms mimicking collagen vascular disease, malignancy, or infective endocarditis.⁷⁰

BENIGN PRIMARY CARDIAC TUMORS

Myxomas

Definition, Incidence, and Prevalence

Myxomas are the most common primary cardiac tumors. They are benign. Although myxomas have been reported in both genders and in all age groups, they most often occur in women in the third to sixth decades of life. Myxomas are usually sporadic, but at least 7% occur as part of an autosomal dominant syndrome.

Morphology

Arising from the endocardium, myxomas usually extend into a cardiac chamber. They are generally polypoid, pedunculated lesions with a smooth surface that may be covered with thrombus (Fig. 82-11A). The tumors range in size from 1 to 15 cm, but are most commonly about 5 cm.⁷¹⁻⁷⁴ Myxomas are thought to arise from pluripotent mesenchymal cells. Histologically, myxomas consist of a matrix of acid mucopolysaccharide (Fig. 82-11B).⁶⁸ Myxomas most commonly occur in the atria. Approximately 75% arise in the left atrium, and 15% to 20% arise in the right atrium.⁷³ The remainder of myxomas are located in the ventricles.

Figure 82-11. Left atrial myxoma. **A:** Gross photograph showing large pedunculated lesion arising from the left atrium and extending into the mitral valve orifice. **B:** Microscopic appearance, with abundant acid mucopolysaccharide, scattered collections of myxoma cells, and abnormal vascular formations (*arrow*). (Reproduced with permission from Kumar V, Abbas AK, Fausto N. *Robbins and Cotran Pathologic Basis of Disease*. 7th ed. Philadelphia, PA: Elsevier; 2005.)

Clinical Characteristics

Many patients with myxomas are asymptomatic. The myxoma may be detected by routine screening echocardiography performed for other indications. Asymptomatic myxomas should be excised in order to prevent emboli, valvular dysfunction, or constitutional symptoms.

Patients with myxomas can have a variety of symptoms. In the sporadic form, classic findings include emboli, congestive heart failure caused by obstruction of cardiac blood flow, and constitutional symptoms. These sequelae are related to the location, size, and mobility of the tumor. Because most myxomas arise in the left atrium, systemic embolization is common, occurring in 30% to 50% of cases.^{75–77}

Myxomas also can display signs and symptoms related to cardiac obstruction. Typically, the findings are related to the tumor's ability to impede filling of the ventricles; in such instances, signs and symptoms may mimic those of mitral or TV stenosis. Constitutional symptoms include fever, malaise, rash, weight loss, and myalgia.

Diagnosis

Echocardiography is the imaging modality of choice for diagnosis of myxomas. In cases of diagnostic uncertainty, MRI and computed tomography (CT) may be helpful. Final diagnosis is confirmed by pathologic examination.

Management

Surgical resection is the mainstay of treatment. Great care must be taken to minimize manipulation of the heart before cross-clamping the aorta to reduce the risk of intraoperative tumor embolization. A variety of approaches are available for resection of left atrial tumors. In the absence of other cardiac disease, a minimally invasive or robotically assisted operation can be employed to speed postoperative recovery. The tumor is resected en bloc. Tumors that arise from a relatively well-defined pedicle can be excised without full-thickness excision of a button of atrial wall. The results of surgical excision are good with a low risk of morbidity and mortality (0% to 3%).^{78–80} A variety of approaches are available for resection of left atrial tumors. In the absence of other cardiac disease, a minimally invasive including robotically assisted operation can be employed due to superior postoperative recovery and patient satisfaction, with equal safety and effectiveness.^{81–83}

Other Benign Primary Tumors

Rhabdomyoma

Rhabdomyoma is the most common cardiac tumor in children and the second most common benign cardiac tumor overall.⁷³ Most occur in children younger than 1 year of age. Rhabdomyoma is a benign tumor composed of cardiac myocytes. About one-half of patients with rhabdomyoma have tuberous sclerosis, and about one-half of patients with tuberous sclerosis develop rhabdomyomas.⁸⁴ These tumors occur sporadically or in conjunction with other rare congenital heart malformations.

Rhabdomyomas usually are found deep in the myocardium; they may extend into the cardiac chambers. They are of variable size, ranging from 1 mm to several centimeters. Most rhabdomyomas are multicentric and involve both ventricles. Because of their morphologic appearance and multicentric nature, rhabdomyomas are classified as hamartomas rather than as true tumors.⁸⁵ Pathologically, they are distinguishable from the surrounding myocardium by their firm, gray, nodular characteristics.⁸⁶

Most children with rhabdomyomas display cardiac arrhythmias or obstructive symptoms in the first few days or weeks of life. Rhabdomyomas causing significant intracardiac obstruction to blood flow can result in death within 24 hours of birth; patients with less severe disease may be asymptomatic for years. The diagnosis is usually made by echocardiography. One of the curiosities of this tumor is the well-documented tendency for these tumors to regress.^{87,88}

In most cases these tumors are not resected. Surgical resection is reserved for masses that cause significant cardiac obstruction.^{89,90} Given the multicentricity of the lesions and their limited growth potential, the operative approach is conservative debulking, with the goal being relief of outflow obstruction with preservation of electrical conduction and myocardial and valvular function.

Lipomas

Lipomas are encapsulated masses of adipose tissue that usually arise from the myocardium or pericardium.⁷³ They are usually small but can grow to be massive. Lipomas involving the pericardium may be mistaken for pericardial cysts and may be associated with pericardial effusions. Although most of these tumors are identified after death, they can be diagnosed by echocardiography and MRI. Most cardiac lipomas can be observed. However, lipomas causing obstructive symptoms or arrhythmias should be resected.

Papillary Fibroelastoma

Papillary fibroelastomas are the most common tumors affecting cardiac valves.^{91,92} They usually involve the valves of the left side of the heart, and typically occur in adult patients.⁹³ Although papillary fibroelastomas usually are asymptomatic, when symptoms occur, they are most frequently related to embolization. The tumors are identified by echocardiography. Surgical excision is advised, even in asymptomatic patients.^{91,94,95} When resection is performed, a minimally invasive surgical approach is generally possible.

Malignant Primary Cardiac Tumors

Angiosarcoma

Most malignant cardiac tumors are metastases from other malignancies.⁷⁴ Almost all primary malignant tumors of the heart are sarcomas⁹⁶; angiosarcoma is the most common malignant primary cardiac tumor.⁷³ Angiosarcomas are usually solitary, large bulky masses that originate in the right atrium (Fig. 82-12). They may extend into the right atrial cavity, causing valvular obstruction, right-sided heart failure, or hemorrhagic pericardial effusion with tamponade.⁹⁶ Most of these tumors metastasize, most commonly to the lung, liver, or brain.⁹⁷ Angiosarcomas are very aggressive, and survival after diagnosis ranges from 3 to 15 months.⁸⁵ Given their rapid growth and poor prognosis, surgical resection is rarely successful.

Rhabdomyosarcoma

Rhabdomyosarcoma is the second most common cardiac sarcoma. Like angiosarcoma, it is more common in men.⁹⁸⁻¹⁰⁰ Unlike angiosarcoma, rhabdomyosarcoma does not have a predilection for a particular cardiac chamber.⁷³ It may occur at multiple sites and extend into the pericardium. Patients may have cardiac obstructive or constitutional symptoms. Prognosis is poor, and surgical resection is usually ineffective.

Secondary Cardiac Tumors: Metastases to the Heart

Metastatic tumors to the heart, or secondary tumors, are much more common than are primary cardiac

tumors. Secondary tumors are usually carcinomas rather than sarcomas because of the relative frequency of these cancers.⁹⁶ Hematogenous spread is the most common mode of metastasis, but lymphatic spread and direct extension also occur.

Figure 82-12. Gross photograph of angiosarcoma of the right ventricle. (Reproduced with permission from Kumar V, Abbas AK, Fausto N. *Robbins and Cotran Pathologic Basis of Disease*. 7th ed. Philadelphia, PA: Elsevier; 2005.)

Symptoms occur most commonly in patients with pericardial metastases rather than intramural or intracavitary involvement. The symptoms associated with metastases are congestive heart failure and arrhythmias. Metastases to the heart should be suspected in patients with known neoplasms who develop congestive heart failure.

Carcinoma of the lung and breast may directly invade the parietal and visceral pericardium, causing myocardial restriction and pericardial effusion.⁹⁶ Melanoma commonly metastasizes to the myocardium, as do leukemia and lymphoma. The treatment of metastatic tumors depends on the tumor type and symptoms. Given the late stage at which cardiac metastases occur and the poor prognosis, few of these patients are candidates for cardiac surgical intervention. Lymphoma and leukemia may respond to chemotherapy or radiotherapy. Symptomatic malignant pericardial effusions may be drained by creation of a pericardial window, temporarily relieving symptoms.

Chapter 83

Ischemic Heart Disease

Jonathan W. Haft

Key Points

- 1 Because of its unique physiology, the heart is particularly susceptible to ischemic injury.
 - 2 Atherosclerotic plaques cause ischemia from chronic flow limitations or from unstable plaque rupture.
 - 3 Patients with coronary artery disease will present with either chronic stable angina or an acute coronary syndrome (ACS), which consists of unstable angina, a non–ST-segment myocardial infarction, or an ST-segment myocardial infarction.
 - 4 Several well-described complications from myocardial infarctions must be anticipated and recognized early.
 - 5 Medical treatment of coronary artery disease includes lifestyle modifications and medications to slow the progression and stabilize atherosclerotic plaques.
 - 6 Percutaneous intervention (PCI) of coronary lesions has improved dramatically in recent years to include drug-eluting intracoronary stents.
 - 7 Coronary artery bypass grafting (CABG) involves creation of alternative conduits from the systemic circulation to the epicardial coronary arteries.
 - 8 The left internal mammary artery is the superior conduit for CABG.
 - 9 CABG remains superior to both medical treatment and PCI for patients with left main or three-vessel disease or for patients with two-vessel disease involving the left anterior descending artery associated with left ventricular dysfunction.
-

CORONARY ANATOMY AND PHYSIOLOGY

The right and left coronary arteries originate from the aorta just above the aortic valve cusps ([Fig. 83-1](#)). The orifices of the two arteries within the sinuses of Valsalva designate the right and left coronary cusps. The third aortic valve cusp is referred to as the noncoronary cusp. The coronary circulation is traditionally divided into three major territories: The left anterior descending (LAD) and the circumflex territories originate from the left coronary artery, and the right coronary territory usually comes from the right coronary artery.

The origin of the left coronary artery is referred to as the left main and travels posterolaterally to the left behind the pulmonary artery, where it divides into two main branches, the LAD and the circumflex coronary artery. The length of the left main coronary artery is variable, but rarely exceeds 2 cm. Unusually, the left main is absent, where the circumflex and LAD originate from the aorta via two separate ostia.

The LAD coronary artery emerges from behind the pulmonary artery and travels inferiorly within the interventricular groove to the cardiac apex, sometimes wrapping around it onto the posterior interventricular groove. The LAD gives off two different types of branches: diagonals and septals, both of which are highly variable in size and number. The diagonals take off at acute angles and perfuse the anterolateral surface of the left ventricle. Septal branches, the first of which is typically quite prominent, emerge at a right angle from the LAD and supply the interventricular septum. The LAD is the most prominent of the three coronary territories described, and carries approximately 50% of left ventricular myocardial blood flow, supplying the anterior, anterolateral, septal, and apical walls.

The circumflex coronary artery continues from the left main coronary and travels within the posterior atrioventricular groove. Branches from the circumflex are called obtuse marginal arteries, and also vary greatly in size and number. In 80% to 90% of people, the terminal branch of the circumflex supplies the posterolateral wall of the left ventricle. In the remaining 10% to 20%, the circumflex continues to the

posterior interventricular septum and terminates as the posterior descending artery (PDA). This is referred to as a left dominant heart, where the left main coronary artery is supplying the posterior interventricular septum. Some patients will have a third branch of the left main referred to as the ramus intermedius, or intermediate branch. If present, this vessel is typically large, and supplies much of the anterolateral wall of the left ventricle.

The right coronary artery originates from the anterior right sinus of Valsalva and descends in the right atrioventricular groove. One or more acute marginal branches feed the right ventricular free wall. In 80% to 90% of patients, the right coronary artery continues to the posterior interventricular septum and supplies the PDA and often a variable-sized right posterolateral artery. This is referred to as a right dominant heart. Near the origin of the posterior descending branch, a small characteristic vessel can be seen supplying the atrioventricular node. This branch can become important in acute right coronary artery occlusions, resulting in life-threatening heart block and bradycardia. A small proximal branch of the right coronary artery supplies the sinus node on the anterolateral surface of the superior vena cava.

Anomalous origin of the coronary arteries is common, occurring in 0.3% to 1% of the population, and their anatomy is varied and complex. Rarely, the left coronary arises from the pulmonary artery. This pathology is diagnosed in infancy, as the myocardium becomes profoundly ischemic when pulmonary vascular resistance falls and myocardial perfusion decreases. If left uncorrected, it is universally fatal. The coronaries may also originate from atypical aortic root sinuses, and their trajectory is variable. The most worrisome problem occurs when the LAD or left main coronary artery originates from the right sinus of Valsalva. When the LAD travels posteriorly and to the left, it courses between the pulmonary artery and the aortic root. This trajectory is described as “malignant” because of the potential for compression between the great vessels, particularly during accentuated wall stress, such as with exercise. Although there is little evidence, it is generally accepted that a revascularization strategy should be considered in symptomatic patients with “malignant” coronary anomalies or in asymptomatic patients with demonstrable ischemia on noninvasive testing.¹

Figure 83-1. Anatomy of the cardiac circulation. A: Anterior view. B: Posterior view.

Venous anatomy is more predictable, and very little pathology within this system is encountered. Three named venous branches can be identified: the middle cardiac vein in the posterior interventricular groove, the posterior cardiac vein along the obtuse margin of the heart, and the great (or anterior) cardiac vein along the anterior interventricular groove. All three drain into one confluence known as the coronary sinus along the posterior atrioventricular groove (Fig. 83-1). The coronary sinus empties posteriorly into the right atrium between the inferior vena cava and the annulus of the tricuspid valve. In addition to these identifiable named veins, the myocardium also drains directly into all chambers of the heart via thebesian veins.

1 Myocardial work consumes an enormous amount of energy substrate. In fact, only 10% to 20% of myocardial energy requirements are related to basal functions; the remainder is utilized during the continuous energy-dependent calcium mobilization and myofilament cross-linking from cyclic contraction and relaxation. Even at rest, the heart maximally extracts oxygen delivered from the bloodstream, leaving venous saturation in the coronary sinus typically 20% or less. Thus, increased energy requirements must be met with augmentation in blood oxygen delivery. Contrarily, other less oxygen-dependent tissues, where venous saturation can be as high as 80%, can extract additional oxygen during stress. When insufficient supply of oxygen is available, as may be the case with extreme consumption or limited blood flow, anaerobic metabolism cannot generate enough energy substrate to perform myocardial contraction.² As a result, cardiac function deteriorates immediately and can be observed clinically essentially within heartbeats. Increases in cardiac oxygen consumption must be met with proportional increases in myocardial blood flow.

The heart and its coronary circulation have a unique capacity to dramatically increase blood flow, and thus oxygen delivery, during periods of increased needs.³ While basal coronary blood flow is approximately 10 mL/kg, this value can increase up to sixfold with exercise by autoregulatory mechanisms and feedback loops. Specifically, adenosine accumulates from the breakdown of the energy substrate adenosine triphosphate (ATP). Vasodilatory receptors within the media of coronary arteries are particularly avid for adenosine, increasing blood flow to myocardial regions with increased energy consumption. In addition, increased myocardial activity activates nitric oxide synthase within coronary endothelial cells, producing the powerful vasodilator nitric oxide. By immediately altering the vessel diameter and thus changing the resistance properties of epicardial vessels, these two short-acting mediators can rapidly alter coronary flow rates to meet changing energy requirements.

In addition to the high metabolic requirements of the heart and its dependence on responsive changes in blood flow, the coronary circulation is further uniquely challenged. During systole, increased cavitory pressure compresses intramyocardial vessels and virtually eliminates forward flow. As a result, blood flow to the left ventricle occurs only during diastole, so that myocardial perfusion depends not only on coronary arterial patency and caliber, but also on the diastolic pressure gradient and the duration of diastole. Tachycardia not only increases oxygen consumption, but also reduces the time available for myocardial perfusion, increasing the demands for epicardial flow. The rise in ventricular diastolic pressure seen in heart failure also reduces perfusion pressure and can jeopardize ischemia in vulnerable territories. With an understanding of cardiac perfusion needs and mechanics, it is apparent why occlusive lesions in coronary arteries can restrict blood flow, producing ischemia and infarction.

CORONARY ATHEROSCLEROSIS

Atherosclerosis is a progressive multifocal disease of medium and large muscular arteries of the systemic circulation. Atherosclerotic plaques or atheromas can occur anywhere in the systemic circulation, but tend to present clinically in varying quantities in the coronary circulation, carotid arteries, splanchnic vessels, and lower extremities. The lesions tend to occur predominantly at vessel bifurcations, sharp curvatures, and other regions creating pressure wave reflections and recirculation.⁴ All plaques consist of smooth muscle proliferation and intracellular and extracellular lipid deposition within the arterial intima (Fig. 83-2). The predecessor “fatty streaks” seen in the first two decades of life are small and unobstructing. However, under certain clinical circumstances, endothelial injury from cigarette smoke, hypercholesterolemia, hyperglycemia, hypertension, or other causes of inflammation initiates a cascade of events. These include endothelial dysfunction with expression of adhesion molecules, which bind circulating inflammatory cells like monocytes. The activated monocyte transmigrates into the vessel wall and ingests accumulated lipids. In turn, they release cytokines, which

enhance endothelial cell adhesion molecule expression; alter endothelial cell nitric oxide production, promoting vasoconstriction and platelet activation; and stimulate activation of other inflammatory cells including neutrophils and T lymphocytes. The activated monocytes accelerate further lipid accumulation and smooth muscle cell proliferation. The end result is an enlarging plaque encroaching on the arterial lumen, separated from the bloodstream by a collagen-rich fibrous plaque.

Figure 83-2. The atherosclerotic plaque. **A:** The normal muscular artery consists of an internal intima with endothelium and internal elastic lamina. The smooth muscle of the vessel wall is in the media, and the thin adventitial layer contains connective tissue and the vasa vasorum. **B:** The first phase of an atherosclerotic lesion consists of focal thickening of the intima with smooth muscle cells and extracellular matrix and an initial accumulation of intercellular lipid deposits. **C:** Extracellular lipid may also develop. **D:** Intercellular and extracellular lipid in the earliest phase is referred to as a fatty streak. **E:** A fibrous plaque results as fibroblasts that cover the proliferating smooth muscle cells laden with lipids and cell debris continue to accumulate. The lesion becomes more complex as continuing cell degeneration leads to an ingress of blood constituents and calcification.

2 Within the coronary circulation, atherosclerotic stenotic lesions are generally restricted to the proximal regions of the large epicardial coronary arteries. In particular, stenosis found in the LAD and circumflex vessels are frequently isolated, short, and in the proximal segments. The right coronary artery, however, develops diffuse obstructions, although rarely extending into the posterior descending or intramural branches. For reasons that are unclear, atherosclerosis is rarely found within intramyocardial segments of the coronary arteries. Symptoms from these atherosclerotic plaques can occur from a variety of proposed mechanisms. First, the lesion can cause flow limitations, particularly when the luminal cross-sectional area is reduced by at least 75%. With this degree of obstruction, the vasodilatory reserve required during increased myocardial demand is restricted, resulting in transient myocardial ischemia until demand returns to baseline, also known as exertional angina. The

atherosclerotic plaque also causes coronary ischemia when the lesion becomes unstable. The fibrous plaque can fracture or rupture, exposing the bloodstream to the highly thrombogenic internal plaque contents. This can lead to complete epicardial thrombosis, the presumed mechanism of ST-segment elevation myocardial infarction (STEMI). Additionally, subtotal plaque disruption can cause vasoconstriction, platelet activation, and embolization, resulting in ischemia without total occlusion of the epicardial vessel. This is the presumed mechanism of unstable angina and non-ST-segment elevation myocardial infarction (NSTEMI). Some plaques are more prone to rupture than others, and the composition of the fibrous cap may be an identifiable feature of an unstable lesion. Activation of inflammatory cells may increase the activity of matrix metalloproteinases, which degrade components of the fibrous cap. Some theorize that certain stressors can stimulate activation of these inflammatory cells, such as acute infections, extreme cold, and even emotional distress.⁵ The inflammatory component of coronary artery disease has been demonstrated by the strong relationship between C-reactive protein and the incidence of acute myocardial infarctions.⁶

Although the characteristics, locations, and severity of lesions in each person can vary, a number of established risk factors appear to predispose to atherosclerosis. These include advanced age, family history, male sex, hypertension, diabetes mellitus, dyslipidemia, and cigarette smoking. Recognizing the presence of these risk factors can help identify patients at risk of coronary atherosclerosis. In addition, some of these risk factors are modifiable, and simple interventions can reduce their risk of future cardiac events.

Hypertension is strongly associated with the development of atherosclerotic heart disease and the risk of death from cardiovascular causes. Although the mechanism is uncertain, it has been suggested that an increase in shear stress at particular vessel locations may injure the vascular endothelium, predisposing to lipid deposition and plaque development. Systolic hypertension appears to be more predictive than diastolic hypertension, particularly in elderly patients. Numerous interventions can control hypertension, but the most effective appears to be lifestyle modifications including reduction in dietary sodium, exercise, and weight loss. Several classes of medications are used for blood pressure control, and each is variably efficacious in different populations of patients.⁷ Unequivocally, reduction in elevated systolic blood pressure reduces the risk of death from cardiovascular disease, and in particular of atherosclerotic coronary artery disease.

Patients with diabetes are two to four times more likely to have coronary artery disease, and even more so when they are insulin dependent and in diabetic women. In addition, patients with diabetes and coronary disease have worse outcomes than age-matched nondiabetics. Unfortunately, rigorous control of elevated blood glucose concentrations by insulin does not appear to affect coronary mortality as well as control of other risk factors such as hypertension, dyslipidemia, and smoking cessation does.⁸

Dyslipidemia is associated with accelerated coronary artery disease. This includes both elevation of total cholesterol levels and an imbalance in the ratio of the subcomponents of cholesterol: high-density lipoprotein (HDL) and low-density lipoprotein (LDL).⁹ HDL levels appear to be protective, as the total HDL level is inversely proportional to the risk for the development of coronary artery disease. Conversely, LDL levels are directly proportional to cardiovascular risk. Importantly, alteration in total cholesterol and the ratio of HDL to LDL by dietary changes, medications, and exercise can reduce the risk of cardiovascular events.¹⁰

Cigarette smoking is one of the most important risk factors for coronary artery disease. Carbon monoxide and nicotine directly adversely affect endothelial cell function. In addition, cigarette smoke can increase LDL levels, reduce HDL levels, increase fibrinogen levels, and increase platelet aggregation. Regular smokers have a four to five times higher rate of cardiovascular death than nonsmokers, and there appears to be a dose relationship, with heavier smokers having a higher prevalence of coronary disease than lighter smokers. Fortunately, the risk of developing coronary artery disease is reduced by 50% after 1 year of smoking abstinence, and at 10 years the risk is no different from that of those who never smoked.¹¹

PATIENT PRESENTATION

The clinical manifestations of ischemic heart disease result from an imbalance of myocardial oxygen supply and consumption. The symptoms and acuity depend on the severity and nature of the patient's occlusive lesions, but also on his or her other medical comorbidities. As many as 25% of patients diagnosed with coronary artery disease have no clear symptoms. The diagnosis is often made based on abnormalities identified on screening tests obtained because of the presence of worrisome risk factors.

3 Chronic stable angina is the most frequent complaint of the patient with coronary artery disease. At rest, coronary blood flow is adequate to meet myocardial demand, and patients are without symptoms. However, during exercise or stress, as myocardial oxygen demand increases, the autoregulatory mechanisms to vasodilate and increase myocardial blood flow are constrained. Significant coronary obstructing atheromas become flow limiting, resulting in an imbalance of oxygen demand and supply. Chest pain develops rapidly and builds up quickly, typically described as tightness, squeezing, constricting, or aching. It is usually midsternal and radiates to the left shoulder, arm, jaw, or neck. The classically described Levine sign with a clenched fist over the sternum is a common finding. Some patients, however, will describe symptoms that are collectively referred to as “anginal equivalents.” These include dyspnea, diaphoresis, nausea, abdominal pain, heartburn, and dizziness or presyncope. Although the differential diagnoses of these “atypical” symptoms are broad, they should prompt the clinician to think of coronary disease, particularly if risk factors predominate. Interestingly, women are more likely to describe atypical symptoms, resulting in late or missed diagnosis of coronary atherosclerosis. Although the clinical manifestations of angina are variable, the pathognomonic feature of chronic stable angina is that the symptoms occur predictably with exertion and are always relieved with rest. Symptoms of patients with coronary atherosclerosis can be categorized according to the Canadian Heart Association Classification scheme. Class I patients have no symptoms, class II patients have angina with significant exertion, class III patients describe angina with mild exertion, and class IV patients have angina at rest.

Acute coronary syndromes (ACSs) refer to a spectrum of accelerated coronary occlusive disease states and include unstable angina, NSTEMI, and STEMI. Approximately 1 million people are hospitalized in the United States each year with a diagnosis of ACS. Unstable angina refers to patients with chest pain or an anginal equivalent that is new in onset, occurs at rest, or occurs with increasing severity and frequency from their baseline chronic stable symptoms, also referred to as crescendo angina. Patients who develop an NSTEMI have evidence of myocardial injury with elevated blood levels of myocardial enzymes (troponin and the MB fraction of creatine kinase). Unstable angina and NSTEMI are important prognostic indicators, as 10% of patients will die of cardiovascular causes within 6 months.

STEMI represents the consequences of large epicardial vessel occlusion, typically associated with plaque rupture. Patients describe a severe retrosternal pain that persists for at least 30 minutes, but usually for several hours. The pain is frequently characterized as crushing, squeezing, or boring, and can radiate down the left arm or into the jaw. Patients with previous chronic stable angina will report that the current pain is similar to but more intense than their baseline symptoms and has not resolved with rest or nitroglycerine. However, many patients that present with an STEMI never had chronic stable angina. Patients will often describe additional symptoms such as diaphoresis, nausea, dizziness, and epigastric pain. In emergency departments, the pain is often mistaken for gastroenteritis or indigestion, particularly in women. Often in elderly patients and those with diabetes, chest pain may not be present at all, and the only symptom associated with STEMI is heart failure from progressive loss of myocardial contractile function. Although improvements in health systems have drastically increased survival from myocardial infarction, mortality for STEMI remains near 10%.

COMPLICATIONS OF ACUTE MYOCARDIAL INFARCTIONS

4 STEMIs can create widespread myocyte necrosis, often resulting in catastrophic complications that require urgent intervention. Anticipation and early diagnosis can improve outcomes. These complications include cardiogenic shock, postinfarct ventricular septal defect (VSD), free wall rupture, and acute mitral valve regurgitation ([Table 83-1](#)).

Cardiogenic Shock

Cardiogenic shock is a state in which cardiac output is insufficient to meet metabolic demands, despite adequate intravascular filling pressures. Between 5% and 10% of patients with acute myocardial infarctions develop cardiogenic shock. A large proportion of these patients progress to shock not upon arrival, but more than 24 hours after initial presentation.¹² Overall mortality is approximately 60%, with very little improvement over recent decades. Treatments include fluids and inotropic agents to optimize myocardial contraction. Insertion of an intra-aortic balloon counterpulsation pump (IABP) can improve coronary perfusion by diastolic augmentation of perfusion pressure. This can have a profound impact by improving contractile function of peri-infarct territories. Although there is significant

afterload reduction afforded by the IABP, cardiac output typically increases by only 15% to 20%. Emergent salvage revascularization can reduce mortality, with sustained benefits seen over long-term follow-up.¹³ When shock persists despite using these aggressive strategies, consideration must be made regarding the patient's candidacy for mechanical circulatory support using ventricular assist devices or extracorporeal membrane oxygenation.¹⁴ While these options may only be available in selected regional medical centers, durable long-term survival can be obtained in a highly selected patient population.¹⁵

Postinfarction Ventricular Septal Defect

A postinfarction VSD is an infrequent complication occurring after fewer than 1% of acute myocardial infarctions. The infarct is most commonly in the LAD territory, with the defect in the distal septum. Alternatively, a postinfarct VSD can form from acute right coronary occlusion, with the infarct predominantly in the posterobasilar septum. They typically present 5 to 10 days following initial presentation, but can occur earlier, particularly if late thrombolytic therapy was administered. The diagnosis should be considered in a patient in whom cardiogenic shock with refractory hypotension and pulmonary edema develops suddenly following a myocardial infarction. On physical examination, an unmistakable holosystolic murmur can be heard over the entire precordium. The diagnosis is confirmed with echocardiography using Doppler techniques to demonstrate flow across the interventricular septum. Right heart catheterization will reveal a step-up in oxygen saturation from the right atrium to the pulmonary artery. Medical therapy involves stabilization to optimize cardiac output and end-organ perfusion. Refractory hypotension is typical, excluding the use of afterload reducing agents. Intra-aortic balloon counterpulsation can occasionally be helpful for afterload reduction and to optimize coronary perfusion. Emergent surgical intervention is required if there is any hope of survival. Infarcted muscle is débrided, and the defect is typically closed using prosthetic material. For surgical candidates, survival rates of approximately 50% can be expected.¹⁶

Papillary Muscle Rupture

Severe regurgitation of the mitral valve can occur after acute myocardial infarctions, with a frequency of less than 1%. The mechanism is related to infarction of the tip or trunk of one of the papillary muscles, with resultant disruption of the mitral subvalvar apparatus and failed leaflet coaptation. Posteroinferior MIs lead to this complication two to three times more frequently than anterior infarctions, presumably because there is more collateral blood flow to the anterolateral papillary muscle compared to the posteriomedial. While chronic mitral regurgitation can be well tolerated through adaptive changes in the left atrium and pulmonary vascular bed, severe acute mitral regurgitation results in immediate heart failure, as the small left atrium offers little compliance for the massive volume overload. Papillary muscle rupture develops typically between the third and fifth days following myocardial infarction, when infarcted myocardium is at its weakest. However, it can present within the first 24 hours. Patients will describe acute-onset dyspnea, pulmonary edema, and possibly signs of cardiogenic shock. The diagnosis should be suspected in any patient after myocardial infarction with a new holosystolic murmur heard at the apex, associated with dyspnea and hypotension. Bedside surface echocardiography typically demonstrates the mitral regurgitation, and the flail leaflet may be seen. For more definitive imaging, transesophageal echocardiography (TEE) can be performed. Not only will the mitral valve pathology be clearly seen, but also alternative diagnoses such as a postinfarct VSD can be excluded. In addition to the treatments typically employed for myocardial infarctions, immediate medical therapy of ruptured papillary muscles involves afterload reduction when tolerated, with infusions of nitroglycerine or nitroprusside. If cardiac output cannot be maintained, intra-aortic balloon counterpulsation can be helpful. Definitive therapy involves prompt surgical correction. Although mortality rates are generally high, there are no survivors without surgical correction.¹⁷ If coronary angiography demonstrated occlusive epicardial lesions in territories other than the acute infarction, simultaneous coronary bypass grafting can be performed. Under most circumstances, the diseased mitral valve is excised and replaced. Because the ventricular cavity is typically small, the valve is usually replaced with a low-profile mechanical prosthesis to avoid left ventricular outflow obstruction from the protruding struts of stented bioprosthetic valves.

Table 83-1 Complications of Acute Myocardial Infarctions

Complication	Diagnosis	Treatment
Cardiogenic shock	Echocardiography, pulmonary artery catheter	Inotropes, intra-aortic balloon pump, VAD
Ventricular septal defect	Echocardiography, cardiac catheterization	Surgical ventricular septal defect repair
Papillary muscle rupture	Echocardiography	Surgical valve replacement
Ventricular free wall rupture	Echocardiography, ventriculography	Emergent repair of ventricular defect

Ventricular Free Wall Rupture

Ventricular free wall rupture after myocardial infarction is infrequently encountered clinically, likely because of the exceedingly high mortality. The actual incidence is unknown, but may represent up to 30% of all deaths after acute myocardial infarctions. Like postinfarct VSD and papillary muscle ruptures, they tend to occur between the third and sixth days after infarction, when the myocardium is at its weakest. Free wall ruptures can present in essentially one of two ways: (a) a simple full-thickness tear with catastrophic hemorrhage and death from tamponade or (b) a complex serpiginous tear, partially contained. The latter is more likely to require surgical intervention, often presenting weeks from the initial infarction with symptoms of delayed cardiac tamponade. In rare cases, it is completely contained and may go unrecognized until a pseudoaneurysm develops, which is often diagnosed at a later date. Patients with free wall rupture will typically present with cardiogenic shock and may have features suggesting tamponade. Echocardiography will demonstrate a large pericardial effusion, frequently with echo-dense clot or ventricular wall defects. Urgent surgical intervention is required, often without coronary angiography or other time-consuming diagnostic tests. Once the pericardium is opened and cardiac tamponade is relieved, hemodynamic stability is often achieved. The site of hemorrhage is identified by the necrotic-appearing myocardium and adherent thrombus. The defect can be closed with large mattress sutures reinforced with Teflon felt strips. Care must be taken while tying the suture, as the necrotic muscle is weak and friable. Some have advocated covering the defect with a large Teflon felt patch using biologic adhesives, avoiding sutures altogether.¹⁸ Whatever the technique, outcomes are likely determined by the hemodynamic status of the patient prior to arrival in the operating room and the quality of the remaining viable myocardium.

Figure 83-3. The electrocardiogram in an acute myocardial infarction.

DIAGNOSIS

The initial diagnostic tool for patients presenting with chest pain is the resting electrocardiogram (ECG). Although the majority of patients with chronic stable angina will have a normal ECG pattern, evidence of previous myocardial infarctions may be identified, either with the presence of Q waves or conduction abnormalities. Patients with an acute myocardial infarction may demonstrate ST-segment elevation ([Fig. 83-3](#)), prompting urgent intervention. Occasionally, more subtle ECG findings may provide clues that the chest pain is ischemic in etiology. Although nonspecific, these changes may

include mild ST-segment depression or T-wave inversions.

During a myocardial infarction, the dying myocytes release enzymes specific to cardiac muscle into the bloodstream. These enzymes can be detected from laboratory analysis and are pathognomonic of myocardial infarction. The MB fraction of creatine kinase is cardiac specific and rises within 8 to 24 hours of infarction and returns to baseline within 2 days. Cardiac troponin has even greater specificity and serum levels rise faster than creatine kinase, improving both the speed and accuracy in the laboratory diagnosis of an acute myocardial infarction in the absence of clear ECG changes.¹⁹

For asymptomatic patients, or those with chronic stable angina, the most widely used diagnostic test to evaluate for coronary artery disease is exercise electrocardiography, or a “stress test.” Using standardized protocols, patients are exercised on a treadmill while the 12-lead ECG is continuously recorded. Alternatively, for those patients unable to walk, a bicycle ergometer may be used. Testing is continued until patient symptoms are noted or until the development of significant downward-sloping ST-segment depression, suggesting myocardial ischemia (Fig. 83-4). The diagnostic accuracy of exercise stress ECG testing can be enhanced with myocardial perfusion imaging. Several radioactive tracers are used clinically, the most frequent of which is thallium-201. Because of its similarities to potassium ions, it is taken up preferentially by viable cardiac myocytes. Its distribution within the myocardium is proportional to the rate of perfusion. During stress, regions of underperfused myocardium will take up less thallium, resulting in a visible defect. Following a period of rest and reperfusion, thallium uptake normalizes, demonstrating a “reversible defect.”

Figure 83-4. Electrocardiogram during an exercise test showing precordial leads V₁ through V₆. **A:** During exercise, depression of the ST segment and ischemia are seen in leads V₄ through V₆. **B:** These resolve after exercise is stopped.

In some cases, patients are unable to exercise because of additional physical or psychological limitations. Pharmacologic agents can substitute for exercise by increasing myocardial oxygen demand (dobutamine) or by directly vasodilating coronary arteries (adenosine or dipyridamole), thus demonstrating regions with fixed restrictions in myocardial blood flow. Echocardiography can be used as an alternative to nuclear perfusion imaging to improve the accuracy of exercise ECG testing. Regional changes in wall motion will be observed during myocardial ischemia, followed by restoration of normal myocardial contraction after rest or discontinuation of dobutamine. Echocardiography can also identify valvular abnormalities or other conditions that may influence treatment choices.

Coronary angiography, also known as cardiac catheterization, is the definitive tool for diagnosing coronary atherosclerotic disease. Indications include symptomatic patients with typical angina refractory to medical treatments, patients with significant ischemia on exercise or pharmacologic stress testing, patients with a STEMI, or patients with an NSTEMI and persistent pain despite medical treatment. Patients with valvular heart disease who are scheduled to undergo surgical correction should also undergo coronary angiography to identify coexisting coronary occlusions, which can be addressed at the time of the valve surgery. After percutaneous access is obtained in the femoral, brachial, or radial arteries, preformed catheters of varying sizes are advanced fluoroscopically to selectively engage the ostia of the left and right coronary arteries. Radio-opaque contrast is injected with imaging of the opacified coronary artery. Standardized views are obtained of both the right and left coronary systems to provide different projections to clearly define the vascular anatomy and to quantify the severity of occlusive lesions (Fig. 83-5). Automated computer analysis systems can calculate area reduction, improving interobserver consistency. Additionally, catheters can be inserted across the aortic valve into

the left ventricular cavity, providing information about ventricular pressure throughout the cardiac cycle. Contrast injection for ventriculography can illustrate ventricular systolic function, cavity size, and the presence of left-sided valvular abnormalities. New microtipped pressure sensors can be advanced across coronary lesions and document a clinically significant drop in perfusion pressure, either at rest or after provocation with vasodilating agents.²⁰ In addition, intravascular ultrasound imaging sensors can now be loaded onto tiny catheters and advanced into the left main coronary artery, helping to clarify the significance of lesions that may appear equivocal in severity on standard angiography.²¹

Newer imaging techniques using high-resolution multislice computed tomography (CT) scanning with three-dimensional reconstruction and magnetic resonance imaging are increasingly being utilized. These noninvasive approaches have the potential to improve the safety and convenience of coronary imaging; however, resolution remains inferior to standard coronary angiography. These techniques are often used as screening tests and are frequently followed up with traditional angiography.²²

MEDICAL TREATMENT

5 Medical therapy of coronary artery disease is designed to slow the rate of progression of coronary artery atherosclerosis, to reduce the rate of complications from these lesions, and to control symptoms. Treatments are aimed at slowing plaque growth, reducing risk of plaque rupture, and reducing myocardial oxygen consumption. While advances in pharmacologic agents have improved the treatment of atherosclerosis and reduced mortality, lifestyle modification remains the most important intervention and the most difficult to achieve. These lifestyle modifications include cessation of cigarette smoking, weight loss, dietary control of diabetes, salt restriction, reduction in the consumption of foods high in cholesterol and fat, and exercise.

Medical therapy begins with controlling risk factors that contribute to formation and destabilization of the atherosclerotic plaque. Medical treatment alone is often satisfactory for many patients with coronary artery disease affecting only one or two epicardial vessel territories. Statins can decrease cholesterol levels and improve the ratio of LDL to HDL and have been demonstrated to reduce rates of myocardial infarction and death.²³ Statins also appear to reduce macrophage accumulation within atheromatous plaques, matrix metalloprotease activity, and collagen degradation. Angiotensin-converting enzyme (ACE) inhibitors have been shown to reduce mortality and myocardial infarction in patients with coronary artery disease.²⁴ Aspirin inhibits cyclooxygenase-1 (COX-1) activity and thromboxane production, irreversibly inhibiting platelet aggregation by inhibiting platelet activity, and should be prescribed to all patients unless significant contraindications exist. Aspirin has been shown to reduce death and myocardial infarctions in patients with significant coronary artery disease. By binding the catecholamine-mediated B₁ receptor on cardiac myocytes, beta-blocking agents reduce myocardial oxygen consumption by reducing heart rate and contractility, and increase perfusion by extending diastolic perfusion time. Beta blockers are effective at controlling angina²⁶ and, in selected patients, reduce cardiovascular mortality.²⁷ Nitrates also reduce myocardial oxygen demand by decreasing cardiac preload via venodilation and by reducing afterload via arterial vasodilation. Some epicardial coronary vasodilation will occur, improving coronary blood flow. Nitrates can be given sublingually for immediate relief or as an oral long-acting agent for continuous control of symptoms. Headaches and tolerance are notable side effects. For patients who have refractory angina despite all revascularization and traditional medical options, a newer agent, ranolazine, has recently been introduced. It alters cardiac myocyte membrane ion channel permeability and can relieve angina with few side effects.²⁸

A patient admitted to the hospital with a diagnosis of acute myocardial infarction or possible ACS should be placed in an environment with continuous ECG monitoring and the capacity to perform emergent defibrillation, since these patients are at risk of life-threatening malignant ventricular arrhythmias. Patients with evidence of ST-segment elevation should undergo emergent cardiac catheterization when possible, as will be discussed later. For those patients in which the ECG is normal but an ACS is suspected, a stress test should be performed expeditiously to identify their risk for future coronary events and to identify patients in need of urgent cardiac catheterization.

Unless there is a strong contraindication, aspirin should be administered immediately, ideally chewed to increase the rate of bioavailability. Typically, aspirin is given by emergency transport personnel. Patients may be instructed by 911 operators to take aspirin if they describe chest pain. Institution of oxygen therapy is important to maximizing oxygen delivery, particularly for patients in whom hypoxemic respiratory dysfunction is also present. Intravenous nitroglycerine as a continuous infusion is typically effective at controlling symptoms of pain, which is essential in reducing unnecessary myocardial strain. Small randomized trials have suggested that nitroglycerine can reduce hospital mortality, although this has not been validated in larger trials.²⁹ When necessary, narcotics should be added, as unrelenting pain not only increases myocardial oxygen consumption, but also may contribute to plaque instability. Beta-blocking agents can reduce myocardial oxygen consumption but can also exacerbate heart failure, particularly in the setting of severely decreased systolic ventricular function. They should be considered cautiously in hemodynamically stable patients. ACE inhibitors reduce

mortality after acute myocardial infarctions, particularly those with decreased ventricular function.³⁰ Benefits are not just restricted to the afterload reduction effects. Some evidence suggests they have a role in alteration of the myocardial intercellular matrix and scar formation.³¹

Anticoagulation is among the most important interventions in patients presenting with an acute myocardial infarction. In recent years, patients with myocardial infarctions were placed on newer antiplatelet glycoprotein (Gp) IIb/IIIa inhibitors, which affect adenosine diphosphate (ADP)-mediated platelet adhesion. Thienopyridines are a newer class of antiplatelet agents that act by binding to the ADP receptors on the platelet surface and inhibiting the GpIIb/IIIa pathway. Specific agents include clopidogrel (Plavix) and ticlopidine (Ticlid). There is strong evidence that the addition of clopidogrel to aspirin reduces death, myocardial infarction, and stroke in the setting of ACS.³² Clopidogrel is irreversible and has a long half-life, resulting in bleeding complications, particularly if surgery is required. Surgical intervention should ideally be delayed for 3 to 5 days.³³ Abciximab (ReoPro) is a murine antibody that binds directly to the GpIIb/IIIa receptor on platelet surfaces, preventing fibrinogen binding and activation. The half-life is short, and platelet activity generally returns to normal within 24 hours. Eptifibatide (Integrilin) is a synthetic antagonist of the GpIIa/IIIb receptor and has a half-life of 3 to 4 hours. The benefit of these agents in patients with ACS treated medically is unclear, but they have become routine in the setting of percutaneous treatment of coronary stenoses. Unless contraindications exist, inhibition of the coagulation cascade is also recommended for patients with acute myocardial infarctions. Although standard unfractionated heparin has been used for many years, newer low-molecular-weight agents and direct Xa inhibitors may have advantages and are used with increasing frequency.^{34,35}

With STEMI, significant myocardium is at risk, potentially resulting in either cardiogenic shock or ventricular arrhythmias. Emergency recanalization of acutely occluded vessels can salvage cardiac function and save lives. Various fibrinolytic drugs, which convert plasminogen to plasmin, can be given emergently and restore flow in vessels obstructed by acute thrombus. A number of clinical trials were performed in the 1980s using streptokinase and demonstrated reduced survival when it was given within 12 hours.³⁶ Newer agents are now available including tissue plasminogen inhibitor (tPA) and reteplase, which are faster in onset and may further improve outcomes, although they are more costly.

The main drawbacks of fibrinolytic therapy are bleeding complications and failure of recanalization. Systemic intravenous thrombolytic therapy unquestionably decreases morbidity and mortality after MI and continues to be used in 40% to 50% of eligible patients. The earlier the treatment, the greater the impact, with the greatest benefit accruing in patients treated within 1 to 2 hours after the onset of symptoms.

In 1977, Dr. Andreas Gruentzig performed the first percutaneous intervention (PCI) with balloon angioplasty on a stenotic lesion in the LAD. This pioneer laid the foundation for a revolution in the treatment of coronary artery disease worldwide. Percutaneous treatment of acute STEMI is now standard practice in centers in which this therapy is available, with outcomes that are superior to pharmacologic reperfusion.³⁷ Although percutaneous intervention may be better than fibrinolysis, the treatment requires numerous experienced personnel and highly technologic equipment, which is not always available in every facility. Complex interhospital and intrahospital systems are now in place to improve the efficiency and application of this treatment strategy, and guidelines have defined minimum “door to balloon” times to salvage myocardium at risk.³⁸

PERCUTANEOUS CORONARY INTERVENTIONS

6 Since the inception of percutaneous transcatheter balloon angioplasty (PTCA), catheter-directed treatment of coronary artery disease has evolved into one of the most commonly performed procedures worldwide. Advances in technology have improved outcomes and expanded the indications, particularly for the acutely ischemic heart. Using the same techniques described for cardiac catheterization, small, highly flexible and steerable guide wires can be advanced through the lumen of epicardial coronary arteries. Over this guide wire, balloon-tipped catheters can be advanced and centered across discrete stenotic lesions and inflated to 4 to 10 atmospheric pressures, stretching and dilating the affected vessel (Fig. 83-6). Typically, the vessel tears or cracks at the junction of the plaque and the normal vessel wall. Acute thrombosis or coronary dissection could result in immediate closure of the vessel, often necessitating emergent surgical coronary bypass grafting in approximately 5% of cases. Restenosis is common, occurring in nearly 40% to 50% of patients, either from mechanical elastic recoil or progressive neointimal hyperplasia.

The addition of stents, nitinol scaffolding devices, has nearly eliminated acute vessel occlusion, and the need for salvage surgical revascularization is below 1%. In addition, stents have greatly reduced restenosis rates down to nearly 20% and are used in nearly 90% of percutaneous procedures in the United States. The stents are delivered crimped onto a deflated balloon. With balloon inflation, the stent expands, restoring the vessel lumen to its anatomic dimensions. The stent prevents elastic recoil and coronary dissection, improving immediate outcomes, but the problem of neointimal hyperplasia remains, resulting in the persistent rates of restenosis. Stents have been improved even further by impregnating antiproliferative drugs onto the scaffolds. Sirolimus and paclitaxel are immunosuppressants that act by different mechanisms. Paclitaxel is a mitotic inhibitor, which retards microtubule breakdown. Sirolimus binds intracellularly to FK-binding protein and inhibits interleukin-2 (IL-2) production via the target of rapamycin pathway. Both sirolimus- and paclitaxel-eluting stents have further reduced the rate of target vessel restenosis and the need for repeat interventions.³⁹ However, reports of late stent thrombosis have raised concerns, and indefinite use of antiplatelet regimens has been recommended.⁴⁰

CORONARY BYPASS GRAFTING

Indications

Coronary artery bypass grafting (CABG) is one of the most common and most studied surgical procedures performed in the United States. As one might expect, CABG consumes more resources than any other single cardiovascular procedure. Dozens of multicenter, prospective, randomized trials have been performed comparing the surgical treatment of coronary artery disease to both medical and percutaneous options. Some of these landmark studies will be discussed in detail later in the chapter, as proper understanding of these trials is important in determining appropriate treatment strategies for individual patients. In summary, these studies consistently demonstrate that CABG continues to be the best revascularization strategy, reducing rate of both myocardial infarctions and the need for repeat revascularization in patients with a broad degree of occlusive disease. A task force made up of numerous medical societies including the American College of Cardiology, the American Heart Association, the Society of Thoracic Surgeons (STS), and the American Association of Thoracic Surgeons recently published guidelines on the indications for coronary artery revascularization and made recommendations regarding the mode of revascularization.⁴¹ The group considered a number of variables, including clinical symptoms and mode of presentation, the degree of ischemia determined by noninvasive imaging, and the severity of coronary disease based on angiographic imaging. In summary, patients are more likely to benefit from surgical revascularization if they have worse symptoms, more severe myocardial ischemia, and more extensive coronary artery occlusions. The recommendations are summarized in [Figure 83-7](#), where recommendations are categorized as “appropriate,” “uncertain,” and “inappropriate.” Interestingly, these guidelines have not changed markedly over the last several decades, despite vast improvements in both medical treatment and percutaneous technology. Today, CABG remains the best mode of cardiac revascularization in symptomatic patients.

Standard Technique

7 The basic principles in coronary bypass grafting are to restore normal unimpeded perfusion of ischemic myocardial territories by providing alternative routes for blood flow. Previous approaches to surgically revascularize the myocardium included creation of intramyocardial tunnels and arterialization of the coronary sinus. However, it was the aortocoronary bypass pioneered by a surgeon named Rene Favaloro at the Cleveland Clinic in the late 1960s that revolutionized the treatment of coronary atherosclerosis. The technique has evolved considerably over the decades, and there remains significant variability in how this complex procedure is conducted even today.

The heart is typically exposed via a median sternotomy. This incision allows exposure of the anterior surface of the heart, as well as the great vessels, for initiation of cardiopulmonary bypass (CPB). Except for the severely hypertrophic heart, the entire epicardial surface can be exposed with manipulation and traction on the left ventricle. Alternatively, a left lateral thoracotomy can be used. This limits visualization to the obtuse margin of the heart but can be advantageous, particularly if the patient has previously had a median sternotomy with dense adhesions hazarding catastrophic injury during sternal reentry. Another alternative has been a limited left anterior thoracotomy, which exposes only a small portion of the anterior wall of the left ventricle, usually limited to revascularization of the LAD. This approach will be discussed later in the section describing minimally invasive approaches to surgical revascularization.

	CABG				PCI		
	No diabetes and normal LVEF	Diabetes	Depressed LVEF		No diabetes and normal LVEF	Diabetes	Depressed LVEF
Two-vessel coronary artery disease with proximal LAD stenosis	A	A	A		A	A	A
Three-vessel coronary artery disease	A	A	A		U	U	U
Isolated left main stenosis	A	A	A		I	I	I
Left main stenosis and additional coronary artery disease	A	A	A		I	I	I

ACCF/SCAI/STS/AATS/AHA/ASNC 2009 appropriateness criteria for coronary revascularization. *Circulation* 2009;119:1330–1353.)

The key to constructing a durable and reproducible anastomosis to small diseased epicardial vessels is creation of a quiet and bloodless surgical field. The advent of CPB using extracorporeal circulation along with cardiac standstill using cardioplegia has allowed precisely this environment. The epicardial vessels are motionless and can be brought directly into the surgical field. Epicardial blood flow is eliminated, allowing direct visualization of the lumen without arterial control, avoiding potential clamp or snare injury to the fragile vessels.

After anticoagulation with 300 IU/kg of heparin is confirmed with an activated clotting time (ACT), the patient is cannulated in the distal ascending aorta. Patients may have significant atherosclerotic disease, and the cannulation site should be carefully inspected for mobile lesions using TEE and manual palpation. Some centers advocate epiaortic ultrasonic imaging for more accurate visualization. After insertion, the cannula is manually deaired and connected to the arterial limb of the CPB circuit (Fig. 83-8). Venous drainage is accomplished with a cannula in the right atrium, typically in the atrial appendage. Bleeding from the cannulation sites is controlled by pursestring sutures around the cannulas. Bypass is initiated by venous drainage into a reservoir, emptying the heart of venous return. Blood is pumped into a membrane oxygenator and returned into the aortic cannula, typically at a blood flow rate of 2.4 L/min per m² of body surface area. With full flow, ventilation of the patient can be discontinued, further improving visualization and minimizing motion in the surgical field. The extracorporeal blood is cooled, creating mild hypothermia, varying from 28°C to 32°C. Systemic cooling minimizes end-organ injury from relative hypotension or hypoperfusion from nonpulsatile blood flow.

After adequate CPB is confirmed, the heart is arrested by applying a clamp across the midascending aorta, proximal to the aortic cannulation site. This clamp isolates the native coronary vessels from the remainder of the systemic circulation. Cardioplegia is then delivered to the myocardium via a needle or catheter in the aortic root. There are a variety of cardioplegia solutions commercially available, but the most important components are dilute blood, cold temperature (8°C to 15°C), potassium at 15 to 30 mM/L, citrate for calcium binding, dextrose for myocardial substrate, and pH buffers. The cold temperature and potassium maintain the heart in diastolic arrest, reducing myocardial oxygen consumption. Cardioplegia is typically delivered intermittently, approximately every 15 to 20 minutes, to provide adequate oxygen and nutrient delivery and to minimize myocardial activity. Additionally, some surgeons utilize cardioplegia delivered in a retrograde fashion via a specially designed balloon-tipped catheter inserted into the coronary sinus. Protocols relying entirely upon antegrade delivery of cardioplegia hazard incomplete myocardial protection, particularly in territories of severe coronary artery stenosis or total occlusions. In addition, an incompetent aortic valve will limit cardioplegia delivery down the coronaries, and leaking into the left ventricle will result in significant ventricular distention. Furthermore, antegrade cardioplegia can be delivered under supraphysiologic pressures from the extracorporeal mechanical blood pumps. This can result in epicardial vessel injury and embolization of atheromatous debris, particularly in the reoperative setting in which old vein grafts often contain mobile and highly friable lesions. The use of retrograde cardioplegia can overcome these limitations, and some evidence suggests outcomes can be improved.

Conduits used for coronary bypass grafting are variable. The oldest and most frequently chosen conduit is the greater saphenous vein because of its availability, accessibility, reasonable size match, the

facility with which vascular anastomoses can be created, and the avoidance of morbidity in harvesting the vein. The adequacy and size of the vein can be assessed preoperatively using ultrasound techniques. Generally, a conduit of 2 to 4 mm in diameter is considered suitable. Alternative veins, such as the lesser saphenous vein and cephalic vein, are infrequently used for coronary bypass grafting because patency rates have been reported to be low. The greater saphenous vein can be exposed with a single long incision, beginning at the ankle, midway between the medial malleolus and the anterior tibial tendon. It is important to handle the vein gently and avoid electrocautery directly on the vein to minimize traumatic or thermal injury to the endothelial cells. The side branches are carefully ligated, and the vein is preserved in a solution of cold heparinized blood, often with vasodilating agents such as papaverine and nitroglycerine. If dissection is minimized and hemostasis is meticulously ensured, the incidence of infection and wound healing complications is generally low. Patients will complain of pain along the length of the incision, but this typically resolves after several weeks.

Figure 83-8. Instrumentation for cardiopulmonary bypass.

In more recent years, minimally invasive approaches using endoscopic techniques can harvest the entire length of the greater saphenous vein with three small incisions. After exposure of the vessel at the knee, a blunt dissector is used to create a tissue plane, which is then expanded with CO₂ insufflation. Direct visualization with magnifying endoscopic lenses allows identification and ligation of side branches (Fig. 83-9). The dissection proceeds both proximally and distally, until the vein has been fully mobilized. Small stab incisions allow ligation at the groin and the ankle, and extraction of the vein from the initial incision. This technique has reduced pain, has improved patient satisfaction, and appears to reduce hospital readmission from wound healing complications. However, the technique is more time consuming, which can be aggravating for the impatient surgeon. In addition, the disposable equipment is expensive, increasing the costs by approximately \$500 to \$1,000, depending on the manufacturer and negotiated contract pricing. More importantly, a recent nonrandomized report described the use of endoscopic vein harvesting as an independent predictor of vein graft occlusion, hospital readmission for major cardiac adverse event, and mortality, as compared to open saphenous vein harvesting techniques.⁴² This study was in contrast to the previous smaller randomized trials but raises concerns about the use of this strategy. Proponents of endoscopic vein harvesting argue that the observational

trial did not describe the operator's previous experience using minimally invasive harvesting and suggest that many centers remained on the early part of their learning curve. In addition, newer technology now allows for safer delivery of bipolar electrocautery, minimizing the potential for heat transmission and endothelial injury. In addition, many centers are now administering low doses of heparin before initiating the dissection to reduce the likelihood of in situ thrombus during manipulation of the vein. It is likely that the debate regarding minimally invasive saphenous vein harvesting will continue in the near future.

8 Arterial conduits for coronary bypass grafting have been increasingly utilized because of early neointimal hyperplasia and late accelerated atherosclerosis seen in saphenous vein grafts. The most important of these arterial conduits is the left internal mammary artery, which originates from the left subclavian artery and descends caudally behind the chest wall, just lateral to the sternal edge. It gives off intercostal branches until it terminates distally as the bifurcation into the superior epigastric and musculophrenic arteries. The artery is typically mobilized as a pedicle, left intact at its origin from the subclavian artery. After completion of the median sternotomy, the left hemisternum is retracted anteriorly using an elevating self-retaining retractor ([Fig. 83-10](#)). Under direct visualization, the mammary artery, its accompanying paired veins, and a small swath of chest-wall soft tissue are gently separated from the remaining chest wall. Intercostal branches are controlled with clips and divided sharply or with cautery. The dissection proceeds proximally to the subclavian vein and distally to the terminal bifurcation of the internal mammary. A helpful marker identifying the distal extent of the dissection is the appearance of muscular transverse thoracic fibers. Caution must be taken during the proximal extent of the dissection, as the phrenic nerve traverses close posteriorly to the origin of the left internal mammary artery. Once fully mobilized, the internal mammary is divided at the distal bifurcation after heparinization and soaked in a solution of vasodilating agents to overcome spasm from manipulation.

Figure 83-9. Endoscopic vein harvesting. **A:** Endoscope is inserted through a small incision in the knee. **B:** Excellent visualization of the saphenous vein with ample working space. (Images courtesy of Maquet.)

Other arterial conduits are also increasingly utilized, such as the right internal mammary artery, the radial artery, the gastroepiploic artery, and the inferior epigastric artery. The internal mammary artery tends to be spared of atherosclerotic disease, and its patency rates are excellent many years following bypass surgery. As such, many surgeons routinely harvest both internal mammary arteries to take advantage of this biologic privilege. However, utilization of both internal mammary arteries can devascularize the sternum and increase the risk of postoperative sternal wound infections, particularly in obese diabetics.⁴³ The radial artery can be harvested safely in the majority of patients, as a complete palmar arch allows collateral flow to the hand from the ulnar artery. Preoperative ultrasound in addition to a bedside Allen test can reliably identify patients in which hand ischemia precludes radial artery use. Although the radial artery is more resistant to late occlusions typical in saphenous vein grafts, it tends to be prone to spasm from competitive flow originating from subcritically stenosed native coronary vessels. Radial arteries should only be used on coronary targets with at least 70%

proximal stenoses. The inferior epigastric artery has been used as an arterial conduit, but limitations in length and the need for an abdominal incision have diminished enthusiasm. The right gastroepiploic artery can be used, since it has more than adequate length after mobilization off of the greater curve of the stomach. It is left on its pedicle from the gastroduodenal artery and tunneled through a hole in the diaphragm. It is most frequently used to revascularize the posterior descending coronary branch, but will easily reach posterolateral branches as well. Patency has generally been reported to be excellent, but its widespread use is restricted by the additional morbidity of laparotomy and risks of intra-abdominal complications.

Figure 83-10. Elevation of the left hemisternum for visualization of the left internal mammary artery.

Once conduits have been harvested, CPB has been instituted, and cardioplegia infusion has resulted in adequate diastolic arrest, the heart is manipulated to expose the epicardial vessels of interest. Occasionally, the coronary arteries are in fact not on the epicardial surface but run within the epicardial fat or deep within the myocardium. This is common for intermediate branches and the LAD. Careful dissection is often required. If the midportion of the LAD cannot be found, the vessel can be opened at the apex and a small coronary probe can be inserted proximally and palpated to better localize the vessel. Care must be taken to ensure the target has been properly identified. Even the most seasoned cardiac surgeons have mistakenly anastomosed grafts to epicardial veins. Once the target vessel is properly located, an appropriate site for anastomotic construction should be identified. It is important to have a thorough understanding of the angiographic location of significant obstructions to ensure the graft is bypassing all significant lesions. The anastomotic site should ideally be relatively spared of atherosclerotic disease, although in patients with advanced diabetes this is not always possible. The vessel is dissected using a no. 64 sharp scalpel and opened vertically in the midline. This maneuver is among the most essential and challenging, and requires precision and experience. Eccentric incisions, inadvertent incisions in the posterior wall, or incisions in friable plaques can result in stenotic or leaky constructions. The arteriotomy is extended using fine Potts scissors 3 to 4 mm in length. The conduit is beveled to the appropriate length and the anastomosis is created with a continuous running polypropylene suture, usually size 7-0 or 8-0 (Fig. 83-11). Absolute technical precision is crucial, and skills required for these distal coronary anastomoses take practice and experience. A motionless and dry surgical field, 2.5 to 3.5 magnifying loupes, experienced assistance, and a steady hand are essential. Some surgeons use gentle insufflation of CO₂ to clear the field of obscuring blood and to distend the coronary artery to improve visualization of the toe and heel. After completion of the anastomosis, saphenous vein grafts or free arterial grafts can be hand injected with cold saline to visualize patency of the vessel and competence of the construction. Pedicled arterial grafts can be opened, and flow down the target will be easily visualized.

Figure 83-11. Distal coronary anastomosis with saphenous vein conduit. Excellent visualization in a quiet bloodless field is required to achieve a hemostatic and unobstructed graft.

The proximal ends of the grafts are usually connected to the ascending aorta. The grafts are cut to the appropriate length. This maneuver also requires experience, as a short graft will create tension, potentially impinging upon the distal anastomosis, and an excessively long graft may kink. The graft is distended to prevent twisting, and the aortic root is filled by infusing antegrade cardioplegia to help determine optimal graft length. One must take into account the change in geometry as the heart fills after weaning from CPB. In general, the conduits should take a straight trajectory toward their target (Fig. 83-12). An aortotomy is created using a specially designed punch of 4 or 5 mm diameter. The grafts are beveled, and the proximal anastomosis is created with continuous running 5-0 or 6-0 polypropylene. Alternatively, the aortic cross-clamp can be removed after completion of all of the distal coronary anastomoses, and a side-biting partial aortic clamp can be placed. This technique can reduce total cardioplegia time but may increase risk of atheroembolic complications from additional aortic manipulation.

After completion of all distal and proximal anastomoses and the aortic cross-clamp has been removed, the temperature of extracorporeal circulation is warmed. Ventricular fibrillation often occurs but can easily be defibrillated with a single internal shock. Ventilation of the lungs is resumed, and CPB flow is gradually reduced. Careful inspection of myocardial contractility and volume is required during weaning, as transient dysfunction often occurs. It is important to avoid distention of ventricular chambers, which causes unnecessary increased myocardial strain. A period of empty beating reperfusion is often helpful, particularly if the aortic cross-clamp period was prolonged or if the heart was severely ischemic preoperatively. Temporary sinus node or atrioventricular node conduction abnormalities are common, and it is standard to place temporary pacemaker leads on the ventricle, although permanent conduction abnormalities are very rare. Suture lines should be inspected for hemostasis, and cannulas for CPB are removed. Although not essential for routine CABG, pulmonary artery catheters and TEE are helpful in weaning from CPB. Excessive pulmonary artery pressures or new regional wall motion abnormalities can suggest perfusion abnormalities and should prompt careful inspection of the bypass grafts. Once satisfactory hemodynamics are achieved, protamine is administered to reverse the anticoagulation of heparin. A notch in the pericardium to the left of the pulmonary artery must be created to allow unhindered passage of the pedicled left internal mammary artery to its distal target. The pericardium is typically left open after coronary bypass grafting to avoid graft kinking or compression; however, mediastinal and thymic fat can be carefully placed over the aorta and proximal anastomoses to protect them from future sternal reentry. Drains are left within the mediastinum to collect shed blood, and the sternum is closed with steel wires, cables, or plates.

Figure 83-12. Bypass grafts take gentle curving but a direct approach to the coronary targets. The pericardium is typically left open to avoid kinking.

Off-pump Technique

While the use of CPB was essential in allowing safe and reproducible coronary anastomoses, it is now well understood that extracorporeal circulation incites a powerful inflammatory response, activating neutrophils and monocytes to release cytokines and inhibiting the clotting cascade and platelet function. Occasionally, these inflammatory changes can produce clinically relevant capillary leak, pulmonary edema, renal dysfunction, hemodynamic instability, and coagulation dysfunction. In addition, iatrogenic cardiac arrest induced by cardioplegia can infrequently result in myocardial injury and dysfunction. In order to avoid some of these adversities, attempts to perform CABG without the use of CPB have become increasingly popular in the last decade. Interestingly, CABG was originally performed without CPB in the early 1960s; however, it was largely abandoned because technically sound anastomoses could not be reliably constructed. Newer technologies are now available that have made creation of surgical bypass grafts more feasible on the full and beating heart.

The heart is exposed via a median sternotomy, identical to the approach used for standard coronary bypass grafting with CPB. Additional sutures are placed deep within the posterior pericardium, which can be used to facilitate retraction of the heart anteriorly and rightward, exposing the anterior, anterolateral, and obtuse marginal surfaces. Typically, the vessel with the most severe occlusion is grafted first, since occlusion of the vessel will result in the least myocardial ischemia and revascularization of this territory may collateralize other regions and improve tolerance to alternate vessel occlusion. For saphenous vein and free arterial grafts, the proximal anastomoses are performed first to allow immediate revascularization of ischemic territories following completion of the distal anastomoses. A dose of heparin is administered, typically 150 IU/kg, and adequate anticoagulation is confirmed with an ACT. A partial occlusion clamp is placed on the ascending aorta for control. Alternatively, newer sealing systems allow clampless control of the ascending aorta during construction of the proximal anastomoses, and sutureless connectors are available that can variably create satisfactory graft–aorta constructs. Once the proximal connections are complete, the grafts are carefully cut to the appropriate length after identification of the anticipated sites of the distal targets.

Of the potential epicardial vessels, the LAD is the easiest to expose, since it lies anteriorly. Gentle retraction on the pericardial sutures, occasionally along with a pad placed behind the heart, will usually expose the vessel adequately. The diagonal branches are exposed with slightly further rightward retraction. The obtuse marginal vessels can be exposed with the help of a suction device placed on the apex of the heart and slowly and gently retracting the apex anteriorly and rightward. This maneuver must be performed carefully, as cardiac chamber and/or outflow tracts can become compressed. The anesthesiologist must be alerted to and familiar with these maneuvers, as temporary vasoactive infusions may be required. Exposure of the right coronary artery and its branches is often the most challenging. The right ventricle can become compressed with retraction superiorly. The suction apparatus placed on the acute margin can facilitate exposure, as can stiff retraction of the right-sided pericardial edges.

Once the epicardial vessel of interest is identified, a U-shaped epicardial suction stabilizing device is applied around the vessel (Fig. 83-13). This device can reduce myocardial motion in a small region of interest, maintaining reasonable contractility. Silastic tapes loaded on blunt needles are carefully encircled around the proximal and distal portions of the coronary artery and gently retracted for blood flow control. A variable degree of ischemia may be seen on the ECG and TEE. The vessel is dissected and opened in the same way as is done for on-pump techniques. If ischemia is pronounced, small shunts can be inserted in the arteriotomy and the silastic snares released to reestablish some distal flow. Continuous insufflation of CO₂ can reduce obscuring blood from the field. The anastomosis is constructed, and competency is assessed. Electrocardiographic normalization should be seen immediately, confirming graft patency. Once all the grafts are complete, protamine is given to reverse the anticoagulation effect of heparin. Hemostasis is confirmed and closure proceeds routinely.

Figure 83-13. Suction-stabilizing devices allow isolation and immobilization of epicardial coronary targets.

Despite early enthusiasm for off-pump coronary bypass surgery, concerns regarding long-term patency of bypass grafts have prompted investigation into its true benefits and general application. A large multicenter randomized trial recently published investigated short- and midterm outcomes of patients undergoing either standard coronary bypass surgery with CPB or off-pump bypass.⁴⁴ Over 2,000 patients referred for coronary bypass grafting were randomly assigned to undergo standard versus off-pump CABG. All patients were felt to be suitable candidates for both approaches, and all surgeons had previously completed a median of 50 off-pump procedures to ensure competency. The primary endpoints were morbidity and mortality at 30 days and 1 year, and secondary endpoints were graft patency and neuropsychologic testing. Thirty-day mortality was similar in both groups (1.6% vs. 1.2% in off-pump vs. on-pump, respectively; $p = 0.47$), as was the rate of perioperative stroke (1.3% vs. 0.7%; $p = 0.28$). However, at 1 year, there was a higher rate of cardiac death in the off-pump group (2.7% vs. 1.3%; $p = 0.03$). At 1 year, 65% of patients underwent routine cardiac catheterization, revealing a significantly reduced rate of graft patency in the off-pump group (82.6% vs. 87.8%; $p < 0.01$), particularly for saphenous vein grafts (76.6% vs. 83.8%; $p < 0.01$). Neuropsychologic testing was performed to attempt to quantify benefits from eliminating proposed neurocognitive dysfunction attributed to CPB. Fifty-four percent of randomized patients completed neuropsychologic testing at baseline and at 1 year, and interestingly, there were no significant differences observed from baseline to 1 year between off-pump and on-pump strategies. In summary, this important and well-conducted study showed no advantages and potential disadvantages of off-pump surgical revascularization in this selected cohort of patients. While there are valid criticisms of this study, these data certainly suggest that routine use of off-pump CABG is not superior, and perhaps should be reserved to selected populations. This author uses off-pump techniques for patients with a heavily calcified or atheromatous ascending aorta or those with severe renal or hepatic dysfunction.

In addition to off-pump CABG, a variety of “minimally invasive” approaches have been conceptualized. The minimally invasive direct coronary bypass (MIDCAB) involves creating a small left anterior thoracotomy. After entering the chest in the fourth intercostal space and resecting a portion of the fourth costal cartilage, a portion of the left internal mammary artery is mobilized under direct vision. Using off-pump techniques and stabilizing equipment, the internal mammary artery is

anastomosed to the LAD using conventional open instruments. Although experiences at selected single centers have described satisfactory patency and reduced cost, complications, and postoperative length of stay,⁴⁵ the MIDCAB has not achieved widespread application. Technical considerations and exposure have raised concerns about graft patency, and in the era of increased percutaneous intervention, very few patients are referred with isolated single-vessel disease. Some groups have advocated for a hybrid approach, in which the LAD is surgically grafted using the MIDCAB approach and the right coronary and circumflex branches are treated percutaneously.⁴⁶ Robotic systems, such as the da Vinci (Intuitive Surgical, Sunnydale, CA), benefit from high-definition three-dimensional video visualization and precise remotely controlled instruments with 6- or 7-degree freedom of motion. They have been increasingly used in noncardiac surgery, particularly in gynecology and urologic specialties. Some centers have begun using robotic technology to harvest the internal mammary artery along its entire length, followed by a MIDCAB, also known as robotically assisted CABG (RAS-CAB).⁴⁷ Others have gone one step further, performing complete coronary revascularization using robotic instruments: the totally endoscopic coronary artery bypass (TECAB).^{48,49} The procedure has been performed with or without CPB and cardiac arrest. Although in selected centers the procedure appears feasible, the widespread utilization of minimally invasive coronary artery bypass remains in question because of concerns regarding patency, particularly in light of recent evidence regarding off-pump surgery in general. Despite changes in technology, there has been little growth in minimally invasive coronary artery bypass procedures.

POSTOPERATIVE CARE

Most patients after undergoing coronary bypass grafting require very little physician intervention, particularly if the operation was conducted according to the preoperative plan. The use of clinical care pathways is now routine, and they have been demonstrated to reduce morbidity, cost, and length of hospital stay. However, complications can occur, which must be anticipated for early recognition and treatment.

Patients after cardiac surgery are routinely admitted to the intensive care setting. Most centers delay extubation until systemic warming is complete, typically within 4 to 6 hours. This also gives ample opportunity to ensure adequate hemostasis and hemodynamic stability. Many centers routinely use pulmonary artery catheters, or Swan–Ganz catheters, for assessment of intracardiac filling pressures as well as calculation of cardiac output. Cardiac output (CO) can be calculated in one of two ways: thermodilution or the modified Fick technique. Using thermodilution, room temperature saline of a known quantity is injected briskly into the right atrium. As the saline mixes with blood traveling through the right ventricle, blood is cooled. The blood temperature is then recorded in the pulmonary artery over time. A curve is generated, denoting the change in temperature from baseline, and the area under this curve is inversely proportional to the cardiac output (e.g., the higher the cardiac output, the lower the impact the small saline aliquot has on blood temperature). Clinicians should be aware that severe tricuspid regurgitation can interfere with the validity of the thermodilution technique, typically underestimating forward flow. The Fick technique relies on the principle of mass balance proposed by Adolph Fick in 1870. Oxygen consumption (VO_2) must equal the difference in oxygen content of arterial and venous blood times the cardiac output. Assumptions can be made about oxygen consumption at rest, and arterial and venous oxygen content (CaO_2 and CVO_2) can be calculated by the hemoglobin concentration and oxyhemoglobin saturation:

$$\text{CO} = \text{VO}_2 / (\text{CaO}_2 - \text{CVO}_2)$$

Goals for hemodynamic stability generally include maintenance of a mean arterial pressure between 65 and 75 mm Hg and a cardiac index of at least 2 L/min per m^2 . Outcomes should be individualized, as a chronically hypertensive patient may require a higher arterial pressure to maintain satisfactory tissue perfusion, and a postoperative patient with bleeding from a tenuous aortic suture line may benefit from a more restrictive blood pressure approach. Hypotension is quite common following cardiac surgery and is often related to hypovolemia, as well as vasodilation from systemic warming and an inflammatory response from extracorporeal circulation with activation of vasodilatory mediators. Intravascular hypovolemia is extremely common in the immediate perioperative period. Causes are multifactorial and include capillary leak from inflammation, venodilation from warming, unrecognized and unreplaced blood loss, and excessive diuresis, particularly if osmotic diuretics such as mannitol are given during CPB. Patients may require 2 to 3 L of fluid in the first several hours after surgery. Those with

ventricular hypertrophy and diastolic dysfunction may require additional fluid to maintain cardiac output. Although not essential, the pulmonary artery catheter can be instrumental in guiding fluid resuscitation. While colloids, such as albumin and hetastarch, can reduce the total volume required to maintain stability, there are no prospective randomized data clearly demonstrating its superiority with regard to outcome benefits.

Vasoconstrictors are used to treat hypotension, but should only be initiated if the patient has been adequately fluid resuscitated and myocardial function and cardiac output is preserved. α -Agonists, such as Neo-Synephrine, will increase vascular tone without increasing contractility or heart rate and do not exacerbate dysrhythmias. Similarly, vasopressin has no effect on cardiac function, but uniquely will not increase pulmonary vascular resistance, as there are no vasopressin receptors in the pulmonary vascular bed. Additionally, vasopressin preferentially constricts efferent renal arterioles rather than afferent arterioles, resulting in maintained glomerular filtration and urine output. Norepinephrine, epinephrine, and dopamine are also frequently used to counteract a vasodilatory state. These catecholamines are also inotropic agents, which can be useful if myocardial function is depressed. However, they all increase heart rate and myocardial oxygen consumption and can be arrhythmogenic.

Myocardial dysfunction can occur from stunning after cardioplegic arrest, particularly if the cross-clamp period was long. This can be problematic if systolic function is severely depressed preoperatively. Inadequate myocardial protection from insufficient cardioplegia can also result in catastrophic and unrecoverable postoperative heart failure. Unless the heart is acutely ischemic at the time of surgery, it is unusual to expect immediate improvement in contractility after surgical revascularization. In fact, the acutely ischemic heart often tolerates CPB and cardioplegia poorly. Contractility can be globally severely depressed after emergent coronary bypass grafting in the setting of a sizable STEMI, especially if the patient was in preoperative shock. If cardiac dysfunction and low cardiac output are detected intraoperatively, careful assessment of bypass graft position and patency should be undertaken. This is especially true if new wall motion abnormalities are regional.

Once surgical problems have been corrected, efforts are made to optimize myocardial contractility. Inotropic agents will improve cardiac function and can be easily titrated to the desired effect. Catecholamines, such as dopamine, epinephrine, and dobutamine, are frequently used. All of these agents, through their effects on β receptors, will increase heart rate, predispose to arrhythmias, and increase myocardial oxygen consumption. Nonetheless, these agents are generally safe, particularly at low doses. Phosphodiesterase inhibitors, such as milrinone, also improve contractility and have less effect on heart rate or myocardial contractility. These agents are also vasodilators, and should be used with caution in patients who are hypotensive. Both catecholamines and phosphodiesterase inhibitors exert their inotropic effects by increasing cytosolic calcium. For these agents to be effective, there must be adequate calcium stores. Infusion of supplemental calcium often potentiates the effect of both classes of drugs. Likewise, acidosis decreases the effectiveness of inotropic agents, and normalization of blood pH, either by replacement of sodium bicarbonate or hyperventilation, can have an immediate effect on myocardial function.

When postoperative ventricular dysfunction is entirely related to myocardial stunning, inotropes should be weaned within the first 24 hours. However, if postoperative cardiogenic shock is severe and refractory to high-dose inotropic infusions, insertion of an intra-aortic balloon pump should be considered. Positioned within the thoracic aorta ([Fig. 83-14](#)), balloon pump actuation is timed with the patient's ECG or arterial pressure tracing. Inflation occurs during diastole, augmenting coronary perfusion, and deflates during systole, reducing afterload and increasing cardiac output. Insertion of a ventricular assist device may be beneficial; however, many of these patients subsequently require heart transplantation, so careful patient selection is essential.

Figure 83-14. Intra-aortic balloon pump positioned within the descending thoracic aorta. The device must be positioned to not occlude the left subclavian artery or the abdominal aortic branches.

Postoperative bleeding is infrequent but can occur, especially when patients are taking irreversible platelet inhibitors. Output from mediastinal chest drains is monitored closely, and markers of coagulation are assessed. Coagulopathy should be corrected with appropriate blood component transfusions. Retransfusion of shed blood is generally avoided, as it may exacerbate coagulopathy. Return to the operating room should be considered if drainage exceeds 600 to 800 mL in 4 to 5 hours, without signs of slowing.

Inhibitors of plasminogen can be helpful in reducing postoperative coagulopathy and bleeding complications. There are three agents in this class of drug: ϵ -aminocaproic acid (Amicar, Xanodyne Pharmaceuticals, New Port, KY), tranexamic acid, and aprotinin (Trasylol, Bayer Leverkusen, Germany). The first two agents are synthetic binders of plasminogen or plasmin. Aprotinin is a naturally occurring serine protease inhibitor that can inhibit plasminogen, as well as many other proteases. Although meta-analysis suggested that aprotinin was superior to the other agents,⁵⁰ concerns regarding the safety of aprotinin have been raised, suggesting a higher incidence of renal failure⁵¹ and even mortality.⁵² A subsequent prospective randomized trial concluded that aprotinin was independently associated with a higher rate of death,⁵³ and as such its approval has been halted by the U.S. Food and Drug Administration.

There has recently been great enthusiasm for using a blood conservation strategy. Transfusion of as little as a single unit of packed red cells is independently associated with increased morbidity after coronary bypass surgery.⁵⁴ Efforts to minimize hemodilution using retrograde priming and hemofiltration can be very effective at reducing transfusion rates, but the most important adjunct to reduce blood usage is reduced transfusion triggers. Evidence exists that hemoglobin concentrations as low as 7 g/dL can be safe and are very well tolerated in intensive care unit patients.⁵⁵

Cardiac tamponade is an infrequent but feared complication that can be fatal and is often difficult to diagnose. The classic scenario is a patient with initially high chest drainage that suddenly ceases. The patient then insidiously develops oliguria, followed by low cardiac output and refractory hypotension. Signs such as bulging neck veins, elevated central venous pressure, pulsus paradoxus, and widened mediastinal silhouette on chest radiography may be variably present. Echocardiography can establish the diagnosis by demonstrating a pericardial effusion with right atrial and right ventricular compression. However, it is important to note that echocardiography cannot rule out the diagnosis. Timely diagnosis usually requires experience and a low index of suspicion. Treatment involves

immediate return to the operating room, where removal of the obstructing fluid and clot results in immediate relief of constriction and normalization of hemodynamic parameters. When tamponade occurs late, it may be treatable with percutaneous drains if the pericardial fluid content is thin and without significant clot burden.

Atrial fibrillation is extremely common following CABG, with a frequency of 25% to 30%. Its occurrence is higher for older patients and those with lung disease, and after combined CABG and valve surgery, decreased ventricular function, prolonged aortic cross-clamp period, and more severe hypothermia. Interestingly, the rate of atrial fibrillation does not appear to be reduced after off-pump CABG.⁵⁶ It most frequently occurs between the second and the fourth postoperative day, and can be precipitated by electrolyte imbalances, particularly hypokalemia or hypomagnesemia. If the rate is excessively high or the patient has significant ventricular hypertrophy, atrial fibrillation can result in hemodynamic compromise producing hypotension and oliguria. The most frequently used treatment for postoperative atrial fibrillation is amiodarone. It can achieve adequate rate control after an intravenous load of 150 mg in the majority of patients, with minimal effect on blood pressure or contractility. As a class III antiarrhythmic, amiodarone is also very effective at facilitating conversion to sinus rhythm. When given preoperatively, amiodarone can also reduce the rate of postoperative atrial fibrillation, although bradycardia is more common in protocols that use higher doses.⁵⁷ Beta-blocking agents are also effective at achieving rate control, and when given routinely preoperatively and reinitiated immediately after surgery, they have reduced the occurrence of atrial fibrillation.⁵⁸ Diltiazem is immediately effective at controlling rapid atrial fibrillation, and is typically given as a 5- to 10-mg load, followed by a continuous infusion of 5 to 10 mg/hr. Although it is associated with hypotension, its short half-life makes this complication quite manageable. For atrial fibrillation with rapid ventricular response refractory to amiodarone, beta blockers, and diltiazem, it may be reasonable to add digoxin. This drug should be used with caution, because it is proarrhythmic. Drug concentrations should be followed and potassium levels maintained aggressively. If rapid ventricular response results in significant hemodynamic instability, electrical cardioversion should be performed. Cardioversion may also be considered if atrial fibrillation persists after 24 to 36 hours because of the risk of clot formation within the left atrial appendage. Cardioversion should not be performed if atrial fibrillation has been present for more than 48 hours. If atrial fibrillation is persistent, anticoagulation must be considered and weighed against the potential for postoperative bleeding complications. The vast majority of patients who develop atrial fibrillation after CABG will revert to sinus rhythm, and the complication rate is generally low. However, atrial fibrillation does increase the length of stay and cost of hospitalization, so efforts to reduce its incidence are necessary.

Deep sternal wound infection involving the bone occurs in approximately 0.5% to 1% of patients. Independent risk factors are obesity, diabetes, immunosuppression, use of both internal mammary arteries, chronic lung disease, and malnutrition. The most frequent organism is *Staphylococcus aureus*, although gram negatives can be seen in diabetics and immunosuppressed patients. Helpful preventative strategies include decontamination of nasal *Staphylococcus* species with mupirocin, preoperative Hibiclens wash, and tight postoperative glucose control. The diagnosis is established with sternal wound drainage and palpable sternal instability. Systemic antibiotics should be initiated and the patient returned to the operating room expeditiously for sternal débridement. Delay could result in mediastinitis with sepsis and shock. Under most circumstances, the chest wall is reconstructed with myocutaneous flaps based on the pectoralis and rectus abdominus muscles.

RESULTS OF CORONARY BYPASS GRAFTING

Overall, the mortality rate following coronary bypass grafting is between 2% and 3%. This number has been progressively declining despite rising median age and worsening severity of disease (Fig. 83-15). Improved outcomes can be attributed to advances in surgical technique, anesthetic approaches, preoperative timing and patient selection, sophistication of intensive care systems, and superior pharmacology, including antiplatelet agents, beta blockers, and statins. Increased competition, both between cardiac surgeons and with percutaneous interventionalists, and public reporting of data have undoubtedly improved efficiency and contributed significantly to better outcomes. Major morbidity is estimated to be 10% to 12%. Risk of stroke is approximately 1% to 2%, renal failure requiring renal replacement therapy is 0.5% to 1%, deep sternal wound infection is 0.5% to 1%, and need for urgent reoperation is 3% to 5%. Overall, median length of hospital stay is approximately 6 days.

Figure 83-15. Unadjusted isolated coronary artery bypass operative mortality: 2000–2009. (This graph is reprinted from the Society of Thoracic Surgeons adult cardiac database 4th 2009 harvest report executive summary. © The Society of Thoracic Surgeons. Used with permission. All rights reserved.)

Table 83-2 Independent Predictors of Mortality Following Coronary Bypass Procedures

Variable	Odds Ratio
Age	1.05 (1.05, 1.05)
African-American race	1.34 (1.23, 1.45)
Chronic lung disease	1.41 (1.35, 1.48)
Diet controlled diabetes	1.15 (1.09, 1.21)
Insulin requiring diabetes	1.50 (1.42, 1.58)
First reoperation	2.76 (2.72, 2.91)
Immunosuppression	1.75 (1.157, 1.95)
Renal failure	1.88 (1.80, 1.96)
Shock	2.04 (1.90, 2.19)
Male gender	0.84 (0.80, 0.89)
NYHA class IV symptoms	1.15 (1.10, 1.20)

The STS maintains a voluntary registry for cardiac surgery outcomes. Participation throughout the United States is extremely high, and the database is generally considered an excellent representation of cardiac surgery outcomes. Overall, coronary bypass procedures have increased in volume, although at a slower pace in recent years, presumably as a result of expanded medical and percutaneous treatments. In 2008, 163,000 isolated coronary bypass procedures were submitted to the STS database. With over 1.4 million individual cases embedded in the dataset, enormous information can be obtained regarding risk factors for mortality and morbidity. Independent predictors of death are listed in [Table 83-2](#) and include coronary reoperation, preoperative shock, dialysis dependence, immunosuppressed state, advanced age, diabetes mellitus, nonwhite race, female gender, previous stroke, advanced heart failure symptoms, peripheral vascular disease, and chronic lung disease. While the presence of these predictors are not contraindications for coronary bypass grafting, these prognostic tools are helpful both in balancing potential benefits from predicted risks and in correctly informing patients, families, and referring physicians. There are two well-described predictive models that can be used to estimate risk of death following coronary bypass surgery. Each model has been created using large voluntary registry data, one from the STS, and one created from the European registry from 128 hospitals across eight countries. Both models incorporate features related to the patients, the nature of their clinical presentation, and the planned operative intervention. Although far from perfect, both models can be very helpful in determining patient selection and preoperative optimization and in tailoring the therapy to the unique clinical circumstances.

Another risk factor for death after coronary bypass grafting that is not included in either stratification model is incomplete revascularization. Incomplete revascularization refers to failure to construct a

bypass graft to a territory natively perfused by a vessel with at least a 50% proximal stenosis. Under most circumstances, the revascularization is incomplete because target vessels were unsuitable for bypassing because they were small, inaccessible, or too heavily diseased. The differences observed are typically not apparent in 30-day survival but manifest as a reduced long-term prognosis. Although the angiographic appearance of potential coronary targets may suggest unsuitability, interpretation of vessel quality is extremely subjective and very difficult to quantify, which is why it has not been incorporated into the two large risk creation models. Nonetheless, the quality of the bypass targets should be considered when weighing the options for treatment of advanced coronary artery disease.

The purpose of coronary bypass surgery is to create unimpeded blood flow to ischemic myocardial territories. While short- and long-term mortality may reflect the adequacy of revascularization, bypass graft patency is a more precise assessment of the technical success of the operation. Patency rates are typically reported based on clinical trials in which routine angiography is performed at regular intervals, excluding biases from studies in which angiography is only performed in symptomatic patients. Saphenous vein grafts are hampered by a higher early graft loss, as much as 20% in the first year. Mechanisms include technical anastomotic problems, graft kinking, inadequate epicardial run-off, vein graft endothelial dysfunction from injury or chronic stasis, competitive flow from relatively unobstructed native coronary flow, and early development of neointimal hyperplasia. Late vein graft occlusion develops at a rate of approximately 5% per year from progressive native vessel disease and the development of accelerated vein graft atherosclerosis. Patency at 10 years is generally 40% to 50%. It remains to be seen if these outcomes improve with advances in statin and antiplatelet agents. As described previously, the internal mammary artery is generally spared of both atherosclerotic disease and early development of neointimal hyperplasia. Not surprisingly, its patency is vastly superior,⁵⁹ although these outcomes may be biased by the fact that the left internal mammary artery is typically placed on the LAD. The higher outflow of this target results in greater flow rates, reducing the risk of stagnation from limited run-off. In addition, its anterior location make it less likely to kink. Patency at 1 year is approximately 95%, and there is very little attrition over time, with 85% to 90% patency at 10 years. In fact, the use of the internal mammary artery is an independent predictor of long-term survival, presumably because of better graft outcomes.⁶⁰ The radial artery is generally intermediate to saphenous vein grafts and the internal mammary artery. Patency rates have been described as 90% at 1 year and 80% to 90% at 5 years. The radial artery is particularly prone to spasm from competitive flow, resulting in a patent but dysfunctional graft, referred to as a string sign. The radial artery should be avoided when stenotic lesions are less than 70%.

COMPARATIVE TRIALS

9 With the advent of coronary bypass surgery in the late 1960s, questions arose as to which patients are appropriate to offer this highly invasive and costly treatment. Three landmark randomized trials were constructed comparing CABG with medical treatment for a variety of patient populations. The Veterans Administration Cooperative Study,⁶¹ the European Coronary Surgery Study,⁶² and the Coronary Artery Surgery Study⁶³ all demonstrated that CABG improves survival as compared to medically treated patients, and the benefits of CABG are enhanced by more severe disease, as well as left ventricular dysfunction. Although these trials are now more than 30 years old and medical and surgical treatments have evolved considerably, the principles continue to apply and are repeatedly described in more contemporary series.

Although these clinical trials definitively demonstrated the superiority of CABG over medical therapy for patients with advanced coronary artery disease, the advent and widespread adoption of intracoronary balloon angioplasty raised the possibility that a less invasive approach to revascularization may be as beneficial as the surgical approach. Several multicenter clinical trials were conducted comparing CABG with angioplasty for a variety of patient populations. The most notable of these studies was the Bypass Angioplasty Revascularization Investigation, or BARI trial.⁶⁴ A total of 1,829 patients were deemed eligible and were randomized to angioplasty or CABG in 18 centers across the United States and Canada. While there were no differences for in-hospital death or 5-year survival, the rate of repeat revascularization was significantly higher in the percutaneously treated patients. Only 8% of patients in the CABG group required repeat revascularization within the first 5 years, as compared to 54% in the angioplasty group. Although survival analysis was intention to treat, 31% of patients in the angioplasty group underwent subsequent CABG. Importantly, subgroup analysis demonstrated a survival advantage at 5 years for diabetic patients treated with CABG as opposed to

angioplasty (80.6% vs. 65.5%; $p = 0.003$). The BARI study demonstrated that surgical revascularization was more durable and resulted in improved survival for diabetic patients with advanced coronary artery disease.

Angioplasty alone carries a restenosis rate of 30% to 40% from at least two mechanisms. One is entirely mechanical, related to elastic recoil, and is seen within weeks of intervention. The other mechanism is related to progressive neointimal hyperplasia, likely occurring as a result of local trauma. Intracoronary stents have reduced the restenosis rate and improved outcomes of percutaneous intervention. In the setting of these advances, several multicenter, prospective, randomized trials were performed, again with the hypothesis that percutaneous intervention would be superior or equivalent to surgical revascularization for patients with advanced coronary artery disease. Among the most prominent of these studies was the SoS, or Surgery or Stent, trial.⁶⁵ A total of 988 patients from 53 medical centers in 11 countries were enrolled based on eligibility criteria, including the presence of multivessel coronary artery disease. Patients were randomly assigned to receive either coronary bypass surgery or percutaneous intervention using intracoronary stents. At a median follow-up of 2 years, 20.7% of patients in the stent arm required repeat revascularization, as compared to only 6% in the CABG arm ($p < 0.001$). Surprisingly, there was also a survival advantage seen with surgery (mortality 4.5% vs. 1.6%, stent vs. surgery, respectively; $p = 0.01$). These mortality advantages persisted with a median follow-up of 6 years (10.9% vs. 6.8%; $p = 0.02$).⁶⁶ Consistent with previous clinical trials, the survival advantage was even more pronounced for diabetics (17.6% vs. 5.4%). The SoS trial was similar to other randomized trials comparing coronary stents with CABG with respect to superior rates of repeat revascularization. However, SoS was unique in describing a mortality benefit. Some have argued that enrollment criteria were much less stringent in SoS, enrolling sicker patients with more complex anatomic lesions. SoS may therefore better reflect “real-world” practice.

Among the biggest limitations of bare metal intracoronary stents is the development of obstructing neointimal hyperplasia resulting in in-stent restenosis, which occurs at a rate of 15% to 30%. Recently, antiproliferative drugs have been incorporated into the platform of stents to inhibit this occlusive process. These drug-eluting stents have been demonstrated in prospective randomized fashion to reduce the rate of repeat revascularization, when compared to bare metal stents. Because of improved outcomes using this new technology, a prospective, multicenter, randomized trial was conducted comparing coronary bypass grafting with a strategy using drug-eluting stents for patients with left main or three-vessel coronary stenosis.⁶⁷ Eighty-five centers in the United States and Europe enrolled patients who met these criteria and whose anatomic disease was determined by both the surgeon and interventional cardiologist to be amenable to either strategy. A total of 3,075 patients were enrolled, but only 1,800 patients were randomized, 897 to CABG and 903 to PCI with the Taxus drug-eluting stent (Boston Scientific). The remaining patients were not felt to be good candidates for both procedures, and 1,077 underwent CABG and 198 underwent PCI. Outcomes of these excluded patients were collected into a separate registry. Of the randomized patients, more patients in the PCI arm had major cardiac or cerebrovascular events at 12 months (12.4% vs. 17.8%, CABG vs. PCI, respectively; $p = 0.002$). The majority of these differences were seen in the rate of repeat revascularization (5.9% vs. 13.5%; $p < 0.001$). The authors also created a numerical system to comparatively describe the complexity of the coronary anatomy. This “syntax” score was higher for chronic total occlusions, bifurcation lesions, heavily calcified vessels, and lesions greater than 20 mm in length. The differences in major cardiac or cerebrovascular events between CABG and PCI were even more pronounced in the subgroup of patients with a high “syntax” score (10.9% vs. 23.4%). This study once again demonstrated that despite improved outcomes of percutaneous treatment of coronary artery disease with drug-eluting stents, CABG remains the best therapy for patients with significant left main and three-vessel coronary artery disease. The benefits of CABG are accentuated for patients with more severe and complex disease.

These important randomized trials have consistently demonstrated that surgical coronary artery revascularization is the ideal technique to reduce symptoms, myocardial infarctions, cardiac-related future hospitalizations, and death in patients with advanced coronary artery atherosclerosis. Improvements in nonsurgical therapy, both medical and percutaneous, have prompted recurring investigations into the comparative efficacy of coronary bypass surgery. Surgical treatment continues to successfully compete, largely because of simultaneous advances in surgical technique, intraoperative patient care, and postoperative management. Despite concerns raised every year that CABG will no longer be performed in the future, outcomes remain superior and as a result, volumes continue to rise. It is likely that surgical revascularization of the ischemic heart will continue to be the dominant strategy

for many years to come.

Chapter 84

Mechanical Circulatory Support for Cardiac Failure

Gordan Samoukovic and Francis D. Pagani

Key Points

- 1 The term “mechanical circulatory support” (MCS*) refers to a broad array of cardiac support devices distinguished by the following important features: location of the pumping chamber of the device, ventricle being supported, and pumping mechanism.
 - 2 Indications for MCS include bridge to recovery, bridge to transplantation, and destination therapy (permanent implantation as an alternative to transplantation).
 - 3 The major types of devices utilized for bridge to recovery are temporary, extracorporeal systems that can be inserted percutaneously.
 - 4 Devices utilized for bridge to transplantation or destination therapy are durable, long-term devices requiring major operative implantation that facilitate patient discharge from the hospital with untethered “hands-free” mobility.
 - 5 Delay in establishing any type of MCS results in a greater acuity and severity of illness increasing the need for biventricular support (as opposed to just left ventricular support alone). Patients requiring biventricular support have a decreased survival secondary to a greater degree of organ failure present at implant.
 - 6 Patient selection is the most important factor in determining outcome of patients who receive MCS.
 - 7 Major adverse events following initiation of MCS are those related to anticoagulation therapy (i.e., bleeding and hemorrhagic stroke) necessary during MCS, infection, right-sided heart failure, and the malfunction of the device (i.e., mechanical or electrical failure and pump thrombosis).
 - 8 The Interagency Registry of Mechanically Assisted Circulatory Support (INTERMACS) is a National Institutes of Health-funded data registry to study outcomes for patients with durable, long-term implantable MCS devices.
 - 9 Major technologic advances in device designs for temporary and long-term durable devices have incorporated continuous-flow rotary pumps with an axial or centrifugal blood flow path.
-

INTRODUCTION

1 The term “mechanical circulatory support” (MCS) refers to a broad array of cardiac support devices. These devices are distinguished by the following important features: (1) location of the pumping chamber of the device (extracorporeal vs. intracorporeal or “implantable”; (Fig. 84-1) (2) ventricle being supported (left ventricular assist device [LVAD] vs. right ventricular assist device [RVAD] vs. biventricular assist device [BiVAD] vs. total artificial heart [TAH]); (Fig. 84-2) and (3) pumping mechanism (pulsatile, volume displacement device vs. continuous-flow rotary device with axial or centrifugal design (Fig. 84-3). Generally, the pumping chamber of short-term support devices is extracorporeal or paracorporeal in location, while so-called “durable” long-term systems are generally intracorporeal (implantable).

INDICATIONS FOR MCS AND DEVICE SELECTION

The spectrum of MCS therapy encompasses several indications for use and a broad range of MCS device designs. Currently, there are three accepted indications for MCS based upon regulatory oversight by the U.S. Food and Drug Administration (FDA), reimbursement criteria set by the Centers for Medicare &

Medicaid Services, and historical use of MCS therapy.

2 3 “Bridge to Recovery” (BTR) refers to the use of MCS in patients who are presenting with acute cardiogenic shock or decompensated heart failure, where the “optimal” medical therapy, including intravenous inotropes and/or vasoconstrictors, has failed. These patients are thought to have an expectation of myocardial recovery following a short period of temporary MCS (generally days to weeks). The short-term utilization of MCS for BTR is the most common application of MCS in the United States.¹ Examples of reversible forms of myocardial injury include acute myocardial infarction, viral myocarditis, or postcardiotomy cardiogenic shock with failure to separate from cardiopulmonary bypass (CPB) following various cardiac surgical procedures. Several types of devices can provide temporary MCS in these circumstances and include an intra-aortic balloon pump (IABP), extracorporeal ventricular assist device (VAD), or extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS).¹ Generally, temporary MCS devices are implanted percutaneously allowing for rapid initiation of support and facilitating removal once cardiac function returns.¹ Certain types of extracorporeal VAD systems require major operative procedures with sternotomy for insertion. These types of systems are generally utilized for postcardiotomy support where access to the mediastinum is facilitated by prior sternotomy performed initially for the open heart operation.

4 The second indication for MCS applies to patients presenting in cardiogenic shock or decompensated heart failure refractory to optimal medical management where myocardial function is unlikely to recover and the patient is considered a candidate for heart transplantation. Durable MCS devices designed for long-term support as a BTT (Bridge to Transplant) and permit untethered patient mobility with discharge from the hospital are appropriate devices for this indication. Implantation of these types of MCS devices requires a major operative procedure usually including CPB and is ideal for patients who are hemodynamically stable with advanced symptoms and/or inotrope dependence in the absence of significant end-organ dysfunction or cardiogenic shock.

Figure 84-1. Classification of mechanical circulatory support devices by location of the pumping mechanism (extracorporeal, paracorporeal, and implantable).

The third indication for MCS applies to hemodynamically stable patients with chronic refractory symptoms of advanced heart failure due to irreversible forms of cardiomyopathy, but who are not eligible for heart transplantation. The application of long-term, durable MCS in this setting is termed “destination therapy” (DT). Similar to the BTT group, DT patients require long-term, durable, and reliable MCS devices permitting untethered “hands-free” patient mobility at home.² Long-term, durable MCS devices are implantable and require a major operative procedure for placement and are ideally placed in patients with significant symptoms of advanced heart failure refractory to optimal medical management but with stable hemodynamics. The survival, functional, and quality-of-life benefit of MCS for DT for the treatment of chronic advanced heart failure was established in a prospective, randomized trial known as the REMATCH Trial (**R**andomized **E**valuation of **M**echanical Assistance in the Treatment of **C**ongestive **H**eart Failure).² This prospective, randomized trial evaluated the use of an implantable LVAD compared with optimal medical therapy for refractory chronic advanced heart failure. LVAD

therapy significantly reduced (relative risk, 0.52; 95% confidence limit, 0.34–0.78 at 1 year) the mortality seen in the control population treated with optimal medical therapy at both 1-year and 2-year follow-up. Despite serious adverse events attributable to MCS from infection, bleeding, and device malfunction, LVAD recipients had an improved survival rate and experienced a superior quality of life compared to the medical therapy group. Currently, patients evaluated for DT must meet the following specific criteria: (1) New York Heart Association Class IV or American Heart Association Stage D heart failure symptoms; (2) a left ventricular ejection fraction of <25%; (3) a peak exercise oxygen consumption of <14 mL/kg/min (if unable to exercise be dependent on intravenous inotropes for 14 days or intra-aortic balloon pump therapy for 7 days); and (4) significant functional limitations despite the use of maximally tolerated doses of drugs outlined in the recent guidelines for heart failure treatment for at least 45 of the last 60 days.³

Figure 84-2. Classification of mechanical circulatory support devices by the ventricle being assisted (A: right ventricular assist, B: biventricular assist, and C: left ventricular assist).

The intended use and indication for MCS significantly influence MCS device selection and use. The decision to initiate MCS must be individualized and based upon the intended use, clinical setting, along with patient variables and condition, type of MCS devices available, and FDA approval and guidelines for use of each specific device. The paradigms of BTR, BTT, and DT have become integrated into the MCS-treatment algorithm, currently delivered by clinicians, regulatory agencies, and insurance payers. These paradigms do not consistently describe all clinical situations and realities of patient care and the separation of patients into BTT and DT populations has been problematic.⁴ During an acute illness, many patients may fall into a gray zone with comorbidities that prevent consideration for heart

transplantation but may reverse over time. Thus, clinicians may not have a clear assessment of heart transplant eligibility at the time of MCS device implant. These patients are frequently categorized as “bridge to decision or bridge to candidacy.” In an attempt to normalize end-organ function that currently precludes long-term heart replacement therapies, these patients are often supported using ECMO or short-term single or BiVADs as a bridge to a durable long-term MCS device. In such cases, even if a contraindication to heart transplant existed at the time of durable MCS device implant, this contraindication may resolve with long-term MCS therapy and the patient may ultimately receive a heart transplant. The category of “bridge to candidacy” is currently not recognized by regulatory agencies but it is likely that indications for MCS will continue to evolve in the future.

TIMING OF MCS INTERVENTION

Cardiogenic Shock and Acute Heart Failure

Although established criteria for initiation of MCS do not exist and there is wide variability in clinical practice,¹ the timing of implant is paramount and directly affects outcomes. Generally, patients presenting with acute forms of myocardial injury have recognizable hemodynamic changes – a cardiac index of less than 2.2 L/min/m², systolic blood pressure less than 90 mm Hg, pulmonary capillary wedge pressure higher than 20 mm Hg, right atrial pressure higher than 18 mm Hg, and evidence of tissue malperfusion and multi-organ dysfunction, despite optimal medical therapy. Patient history and overall clinical setting also need to be considered in the decision to initiate MCS. When patients reach this degree of hemodynamic compromise, the mortality risk is substantial and frequently exceeds 50% at 30 days despite the availability of optimal medical therapy, invasive circulatory monitoring, thrombolysis, and IABP support.^{5,6}

Classification of MCS Devices by Intended Duration of Support and Pump Design

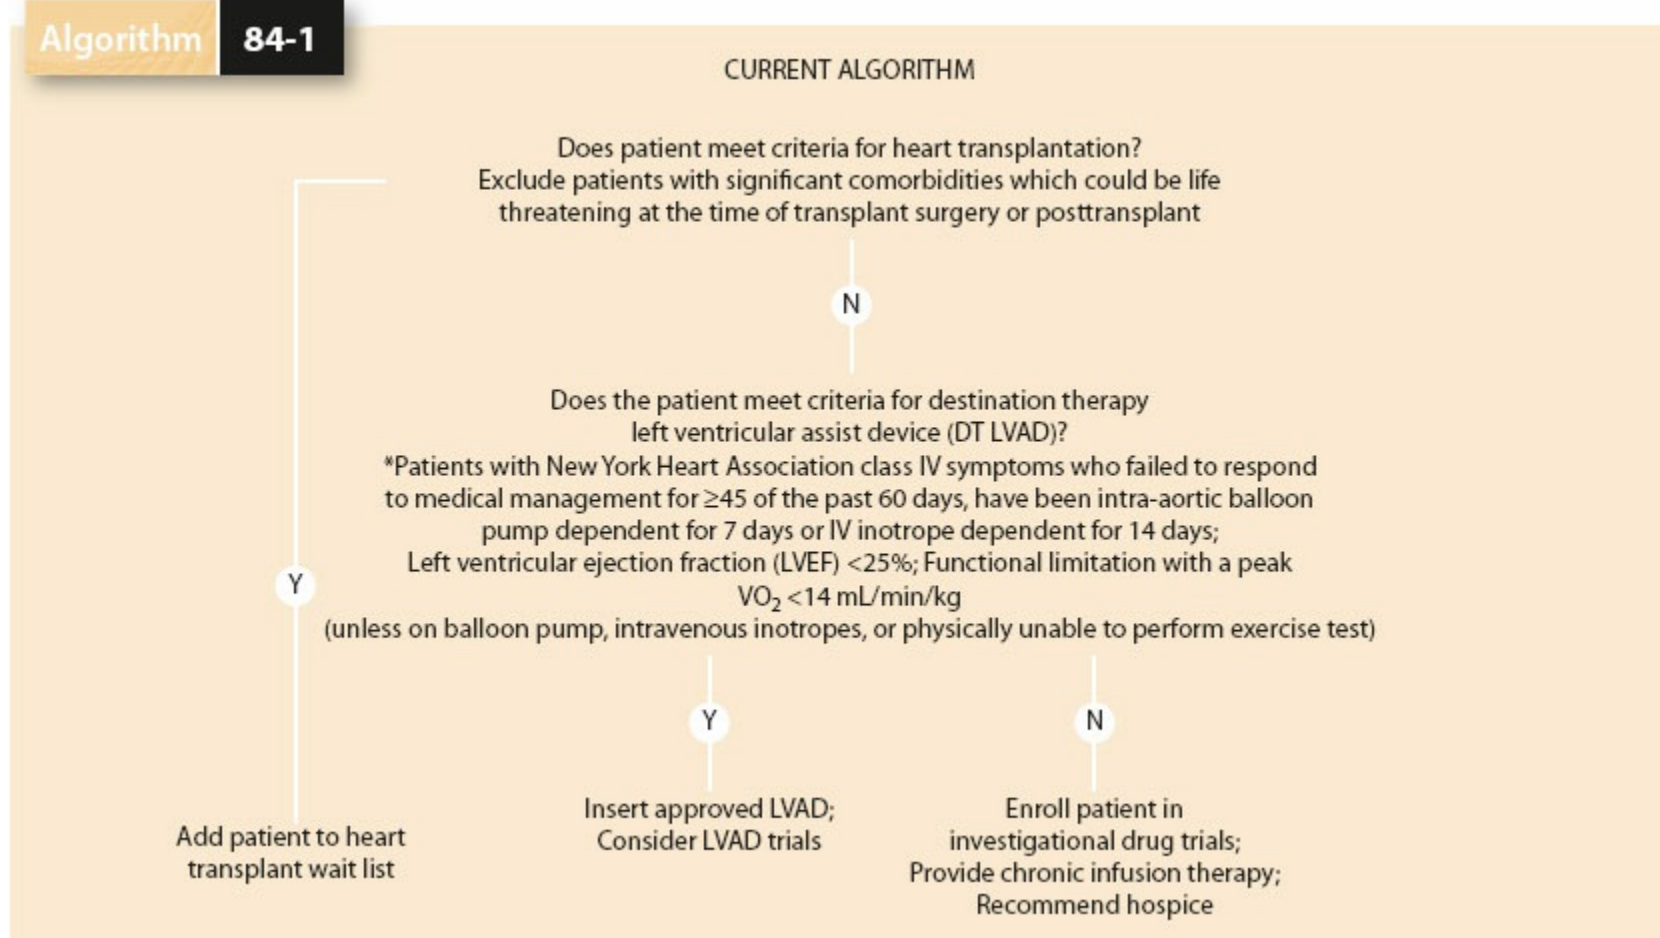

Figure 84-3. Classification of mechanical circulatory support devices by intended duration of support and pumping mechanism (pulsatile, volume displacement, or continuous-flow rotary pumps). (Impella, Abiomed Corporation, Danvers, MA; Thoratec pVAD, HeartMate II, HeartMate III, Thoratec Corporation, Pleasanton, CA; CardioWest TAH, Syncardia Systems, Tucson, AZ; TandemHeart pVAD, CardiacAssist Corporation, Pittsburgh, PA; CentriMag VAD, Levitronix LLC, Waltham, MA; Jarvik LVAD, Jarvik Heart Corporation, New York, NY; HVAD LVAD, HeartWare Corporation, Miami, FL)

Algorithm 84-1

Transplant status is initially assessed to determine appropriate indication for MCS use; BTT vs. DT. (Adapted from Mancini D, Colombo PC. *J Am Coll Cardiol* 2015; 65(23):2542–2555, with permission.)

5 Data from the Abiomed BVS 5000 registry demonstrated that delay in initiating temporary MCS for more than 6 hours in the context of postcardiotomy shock or after failure to separate from CPB is associated with a significant decrease in survival rate; 44% versus 14%.⁷ Delay in instituting any type of MCS with rapid progression of multiorgan failure increases the need for biventricular support as opposed to LVAD support alone.^{8–12} Similarly, an episode of cardiac arrest prior to the initiation of MCS significantly impacts survival rate, decreasing it from 47% to only 7%.⁷

Chronic Heart Failure

More subtle indications to initiate MCS may be present, particularly in the group of patients suffering from chronic advanced heart failure who are being evaluated for BTT or DT. These indications include dyspnea at rest or with any or minimal effort and accompanied by resting tachycardia, progressive organ dysfunction (reflected in worsening renal or hepatic parameters), limited functional capacity, and poor quality of life despite optimal medical management with or without inotrope therapy. Deterioration in end-organ function or progressive decline in functional performance may occur in the absence of a significant change in hemodynamic parameters due to chronic adaptation to low cardiac output. In addition, patients who do not tolerate optimal medical management and experience renal insufficiency or hypotension in the setting of optimal doses of ACE inhibitors or beta blockers, as well as those who do not tolerate inotrope therapy due to refractory ventricular arrhythmias or have life-threatening coronary disease may benefit from MCS therapy (Algorithm 84-1).

Dependence on intravenous inotropes has traditionally been considered the threshold that prompts consideration of MCS^{13–15} (Fig. 84-4). However, patients with advanced systolic heart failure are currently eligible for DT therapy even if they are not dependent on inotropes, provided they meet indications for DT therapy. Only 18% of durable adult LVADs are currently implanted in patients not yet dependent on intravenous inotropes.^{13,14} Low implant rates in ambulatory advanced heart failure (noninotrope dependent) may reflect reluctance of both physicians and patients.¹⁵ Ambulatory patients with advanced heart failure should have ongoing discussions about the trade-offs of living with heart failure in comparison with undergoing LVAD implantation to identify preferences and thresholds for considering elective LVAD therapy. Evidence to guide LVAD use before inotrope dependence is growing.¹⁶

PATIENT SELECTION AND INFLUENCE OF COMORBIDITIES ON

OUTCOMES

6 Patient selection is a paramount in determining outcome in patients requiring MCS. Generally, patients should be excluded from consideration for MCS in situations where cardiac recovery is unlikely and/or heart transplantation and DT are not feasible. Under these circumstances, MCS support is generally considered futile. Other relative contraindications to MCS include irreversible renal, hepatic or respiratory failure, sepsis, or a significant cognitive deficit.

Renal Function

Renal dysfunction in context of MCS has consistently been associated with increased morbidity and mortality rates.^{17,18} It is usually secondary to shock-related malperfusion and high central venous pressures but may also be worsened by drugs frequently used for heart failure therapy. Acute renal failure requiring renal replacement therapy is not necessarily a contraindication to short-term MCS but may be more of an obstacle to successful long-term MCS therapy for BTT or DT. In the setting of cardiogenic shock complicated by acute renal failure, reestablishing normal hemodynamics may facilitate resolution of the renal failure in a relatively short period of time. Duration of cardiogenic shock along with the patient’s baseline renal function, therefore, plays an important role predicting the probability of recovery of renal function.

Figure 84-4. INTERMACS scale for classifying patients with advanced heart failure. Percent of implants by INTERMACS profile. Current U.S. Food and Drug Administration (FDA) approval status and acceptance in the medical community. (Adapted from Mancini D, Colombo PC. *J Am Coll Cardiol* 2015;65(23):2542–2555, with permission.)

Pulmonary Function

Cardiac failure may result in a restrictive pulmonary limitation that frequently improves as MCS aids with removal of interstitial fluid and intrathoracic effusions. Patients with a history of smoking or intrinsic lung disease identified by significant abnormalities on pulmonary function testing warrant high-resolution computed tomography to characterize the lung disease and exclude thromboembolic etiology. Echocardiography is used to rule out an intracardiac shunt. Patients with severe pulmonary disease may have a fixed pulmonary vascular resistance (not responsive to pulmonary artery vasodilators). High fixed pulmonary vascular resistance (generally >6 wood units) represents a contraindication to heart transplantation and thus BTT indication. Perioperative hypoxia as a result of significant underlying lung disease may also contribute to pulmonary vasoconstriction leading to right-sided heart failure following initiation of LVAD support. Moderate elevations in pulmonary vascular resistance can be encountered in patients with cardiogenic shock and does not preclude the successful use of MCS if reversibility or significant decrease in the pulmonary vascular resistance is achieved with inotropes or pulmonary vasodilators.

Liver Function

Previous studies have reported that total bilirubin levels and hepatic cellular enzymes more than three times normal are independent risk factors for adverse outcomes.^{18,19} The etiology of the hyperbilirubinemia may be multifactorial, resulting from any combination of congestive hepatopathy, cholestasis, primary biliary, or infectious or parenchymal disease. Abnormal liver function is often associated with abnormal coagulation and low serum albumin. Attempts should be made to normalize the liver function prior to initiation of durable MCS. The presence of portal hypertension with liver cirrhosis is a contraindication to MCS. Any history of significant alcohol use should be reviewed in potential MCS patients, especially in those showing abnormalities in routine liver function tests.

Patients should also be tested for presence of infectious agents such as hepatitis A, B, or C or other viruses. Liver ultrasonography is an important screening modality for patients with significant hepatomegaly and can rule out infiltrative disease, mass or other pathology that may warrant biopsy. Improvement in hepatic congestion and recovery of synthetic functions of the liver typically occur with institution of MCS.

Right-Sided Heart Failure

Left ventricular dysfunction frequently leads to coexisting right-sided heart failure. Right-sided heart failure is an important cause of mortality and morbidity following initiation of MCS and often necessitates biventricular support.^{8-12,20-22} Patients with a nonischemic etiology of heart failure are three to four times more likely to require BIVAD support. These patients tend to present with early signs of renal, pulmonary, and hepatic dysfunction. BiVAD support is associated with lower survival during both short- and long-term MCS. Preoperative optimization of RV function with a goal of lowering the right atrial pressure lower than 15 mm Hg is important in reducing the need for postoperative RV support. The higher the pulmonary wedge pressure at the time of device implantation, the greater the benefit of LV decompression and hence, reduction in RV afterload that reduces the need for BIVAD support. Early adverse influences of LVAD support on RV function include a reduction in LV pressure over that of RV pressure that causes a leftward shift of the interventricular septum, causing distention of the RV and impairing systolic function of the RV by reducing the significant septal contribution to RV contractility.²³⁻²⁵

Coagulation Parameters

Coagulopathy is a common abnormality encountered in patients with refractory heart failure. An abnormal international normalized ratio (INR) in the absence of warfarin therapy is of added concern, as it may reflect chronically high right atrial pressures, leading to congestive hepatopathy and eventually fibrosis and cirrhosis. Prolonged abnormal INR and low platelet count combined with the use of anticoagulation or antiplatelet therapy are associated with significant perioperative bleeding, requiring multiple transfusions, which frequently lead to elevation of pulmonary vascular resistance, RV failure, hemodynamic instability, and multiorgan failure.^{26,27} In addition, these patients are frequently malnourished and lack substrates for the liver's synthetic pathways, including those of coagulation factors, particularly factor VII. The preoperative screening for coagulation abnormalities should include prothrombin time (PT), partial thromboplastin time, INR, platelet count, platelet aggregation studies, and possibly a heparin-induced thrombocytopenia (HIT) assay. The presence or development of HIT is associated with a high risk of bleeding as well as thrombosis of MCS devices.²⁸

Nutrition

Malnutrition is an important contributor to morbidity among patients on MCS. A serum albumin lower than 3.3 mg/dL appears to increase the mortality rate 6.6 times in the DT population of LVAD patients.^{29,30} Significant nutritional deficiency is often associated with poor wound healing, an increased risk of infection and impaired T-lymphocyte function. Patients whose body mass index is either less than 22 or more than 36 are at risk for perioperative complications. Generally, survival of MCS patients is more adversely impacted by cachexia than obesity. Cachexia is often due to poor appetite due to elevated tumor necrosis factor and other cytokines, limitations in exertion and work of breathing, and early satiety in those with significant hepatomegaly. Delay in instituting MCS therapy may be warranted for several weeks when feasible to allow improvement of the nutritional status, preferably by enteral supplementation. Early aggressive caloric supplementation in the postoperative period is critical in preventing malnutrition and rebuilding nutritional stores.

OTHER IMPORTANT MEDICAL CONSIDERATIONS WHEN INITIATING MCS

Valvular Heart Disease

Abnormalities of the cardiac valves have important adverse consequences in patients considered for MCS and may require repair or replacement in order to successfully initiate MCS and achieve weaning from support. Mild to moderate aortic stenosis in the absence of insufficiency is not a contraindication

to implantation of an MCS device. Severe aortic stenosis, however, should be corrected, preferably with a bioprosthetic valve. This is thought to facilitate future weaning and optimize native heart function if the indication for device implantation is for myocardial recovery. The presence of greater than mild aortic insufficiency can have a significant impact on the effectiveness of MCS therapy as it leads to LV distention and a decrease in subendocardial blood flow. In cases where MCS support is established via LV apical cannulation (more commonly with implantable MCS devices used for BTT or DT), reductions in LV end-diastolic pressure elicited by MCS increase the pressure gradient across the aortic valve and increase the degree of aortic insufficiency, decreasing net forward flow and compromising end-organ perfusion. The presence of aortic insufficiency can be confirmed by perioperative echocardiography and addressed by either AV replacement with a bioprosthesis or repair.³¹ Patients with a mechanical valve prosthesis in the aortic valve position should have the mechanical valve replaced with a bioprosthetic valve prior to institution of LV assistance. During unloading of the LV by an LVAD, the aortic valve may not open and the mechanical valve may be prone to thrombosis. Development of aortic insufficiency after LVAD implantation may be addressed at a later date with aortic valve replacement, via either open surgical or transcatheter aortic valve replacement.^{32,33}

Patients with significant mitral stenosis at the time of initiation of device support may require correction of the valvular problem before implantation of a device depending on device selection and site of cannulation. In the setting of significant mitral stenosis, LV filling is impaired, and VADs requiring apical ventriculotomy for ventricular drainage may experience limitations in device filling. This problem can be circumvented either by choosing a device that can utilize left atrial cannulation or by correcting the underlying valvular pathology (mitral valve repair or replacement with a bioprosthetic valve). Mitral regurgitation likely does not have an impact on the filling of a VAD. In situations where weaning from MCS may be feasible, correction of the mitral pathology (stenosis or regurgitation) is necessary to optimize ventricular function.

Adequate RV function is extremely important to maintain LVAD flow in the early postoperative period. Significant degrees of tricuspid regurgitation (present preoperatively or resulting from septal shift following implantation of an LVAD) can impair the flow of blood from the RV, particularly in situations of high pulmonary vascular resistance. Tricuspid regurgitation and RV dilatation contribute to elevated central venous pressure, hepatic congestion, and renal dysfunction.²⁰⁻²⁵ It is generally recommended that moderate or more degrees of tricuspid regurgitation be repaired at the time of LVAD implant to improve RV performance.

Coronary Artery Disease

Patients with significant obstructive coronary artery disease or patients with postcardiotomy shock following failed coronary bypass operations may experience angina during MCS. Generally, coronary artery disease does not have adverse hemodynamic consequences during the period of MCS. However, the presence of obstructive coronary disease with ongoing ischemia may limit the degree of myocardial recovery and impact the ability to wean from temporary MCS. The presence of coronary disease may contribute to ongoing myocardial ischemia and increase the risk of ventricular arrhythmias for patients supported with temporary or durable MCS.

Perioperative ischemia of the RV may be of hemodynamic significance during initiation of LVAD support. In patients who have had coronary bypass surgery and are candidates for MCS, patent bypass grafts, particularly to the right coronary artery or left anterior descending coronary artery should be preserved to reduce the risk of perioperative RV failure and arrhythmias. In highly selected situations, it may be important to perform a coronary artery bypass to the right coronary artery or left anterior descending coronary artery systems to optimize RV or septal function in the perioperative period. Routine bypass grafting of the right coronary artery is not warranted.

Arrhythmias

Atrial and ventricular arrhythmias are common in patients with cardiogenic shock and underlying cardiomyopathies. These rhythm disturbances generally persist in the immediate postoperative period and subsequently resolve with time as the hemodynamic condition of the patient improves and inotrope therapy is weaned. Recent experience has revealed that the hemodynamic consequences of ventricular arrhythmias in the late postoperative period are generally not life-threatening. In the absence of pulmonary hypertension and elevated pulmonary vascular resistance, patients may maintain life-sustaining degrees of LVAD flows during ventricular fibrillation via Fontan-like (systemic vein to pulmonary artery) circulation.³⁴ In the early perioperative period, some patients with refractory

ventricular arrhythmias may require biventricular support until the pulmonary vasculature resistance drops and a Fontan circulation is tolerated. In situations where weaning from MCS is feasible or planned, elimination of the ventricular arrhythmias with antiarrhythmic therapy is essential.

The majority of patients undergoing implantation of a long-term durable VAD for either BTT or DT indications have an implantable cardiac defibrillator (ICD) in place for either primary or secondary prevention of ventricular arrhythmias as part of their care for advanced heart failure. Generally, these device therapies are continued following VAD implantation. Currently, for those patients who do not have an ICD at the time of VAD implant, International Society for Heart and Lung Transplantation (ISHLT) guidelines recommend routine evaluation for ICD therapy.³⁵ The survival benefit of ICD therapy in the setting of VAD support is, however, controversial with some studies identifying benefit and other studies finding no additional survival benefit over that obtained with VAD implantation alone.³⁶

Intracardiac Shunts

Intracardiac shunts (atrial septal defects or patent foramen ovale) identified by transesophageal echocardiography prior to surgery should be closed at the time of implantation of a VAD to prevent right to left shunting.³⁷ As LV assistance is initiated, left atrial pressure can be reduced compared with right atrial pressures causing shunting of deoxygenated blood from the right atrium into the left resulting in systemic hypoxemia.

PATIENT OUTCOMES AND MAJOR ADVERSE EVENTS FOLLOWING INITIATION OF MCS

7 Survival and occurrence of significant adverse events following initiation of MCS therapy are dependent on the clinical presentation, indication for MCS therapy, and type of device implanted. Bleeding, stroke and thromboembolism, infection, and RV failure are the most frequent complications that occur in the early postoperative period following initiation of MCS and are more commonly encountered when devices are implanted in an emergency situation. Major adverse events most common in the late postoperative period include bleeding and thromboembolic events (e.g., stroke) with or without associated device failure.

Bleeding

Bleeding is a frequent, early complication in patients supported by MCS and may require reoperation in the early postoperative period. Risk factors for bleeding include preoperative hepatic congestion and failure, poor preoperative nutritional status, prolonged CPB times, extensive surgical dissection, reoperative surgery, multiple cannulation sites, decreased platelet function, and induction of fibrinolysis as a result of contact of blood with biomaterial surfaces during CPB and with MCS devices. Even though meticulous surgical technique is of outmost importance, it is important to note that numerous MCS centers employ various surgical techniques with equivalent results.

Nonsurgical bleeding is one of the most common adverse events within the first 30 days after durable VAD implantation.^{38–42} Across studies, the most commonly reported sources of bleeding are epistaxis, GI tract bleeding, bleeding of the mediastinum and thorax, and intracranial hemorrhage.^{38–43} However, the location of bleeding may vary depending on time from operation, with thoracic or mediastinal bleeding having higher, but diminishing, risk in the early postoperative period, with a later risk of GI tract bleeding. Recent data have demonstrated that support with long-term durable MCS is associated with development of acquired von Willebrand's disease caused by high shear stresses within continuous flow rotary pumps that result in degradation of high-molecular-weight von Willebrand multimers and activation of the enzyme ADAMTS13, a zinc-containing metalloprotease enzyme that cleaves von Willebrand factor.^{41–43} Acquired von Willebrand disease has been associated with a high incidence of late bleeding in patients supported with long-term durable VADs manifest at mucosal sites including gastrointestinal bleeding and epistaxis and appears to accentuate previous subclinical arteriovenous malformations, commonly found in patients on MCS.⁴⁴

RV Failure

RV failure occurs in approximately 3% to 30% of patients supported by LVAD support alone. The large variation in occurrence of RV failure is dependent on a number of important patient factors including

severity of illness and timing of intervention. The etiology of RV failure is multifactorial and includes pathologies within the pulmonary vascular bed and/or RV. Factors contributing to RV failure include impaired RV function as a result of intraoperative air embolism, myocardial stunning due to poor intraoperative myocardial protection, ischemia secondary to coronary artery disease, arrhythmias, volume loading, and alteration of RV septal geometry induced by LV unloading. Several studies have demonstrated that factors such as elevated central venous pressure, reduced RV stroke work index, low preoperative pulmonary artery pressures, increased transpulmonary gradient greater than 16 mm Hg, acute decrease in pulmonary artery pressures equal to or greater than 10 mm Hg at the onset of LVAD support, degree of preoperative pulmonary edema, increased need for perioperative transfusions, increasing degree of renal and hepatic dysfunction, female gender, nonischemic etiology, and preoperative temporary MCS support, all increase the need for RV MCS following LVAD implantation.^{8–13,20–25} Among the 484 patients enrolled in the HeartMate II LVAD bridge-to-transplantation clinical trial, 6% required mechanical right-ventricular support while 14% required prolonged inotrope therapy. Multivariate data analysis revealed that a central venous pressure/pulmonary capillary wedge pressure ratio greater than 0.63, need for preoperative ventilator support, and blood urea nitrogen level higher than 39 mg/dL were independent predictors of right-sided heart failure after LVAD implantation.²⁰ Acute unloading of the LV by MCS may cause the septum to shift leftward, increasing RV volume loading and reducing its function.^{23–25} The negative consequences of this phenomenon may be offset by the reduction in pulmonary artery pressures and RV afterload caused by device-mediated LV decompression.^{23–25} Hemodynamic stability can be attained with isolated mechanical LV support in the overwhelming majority of patients, even in those patients with substantial RV dysfunction, if there is effective replacement of left-sided heart function and aggressive treatment of pulmonary hypertension. More recently, the improved perioperative management of elevated pulmonary vascular resistance including the use of inhaled nitric oxide, a specific, potent pulmonary vasodilator, in combination with milrinone, isoproterenol, or dobutamine has significantly reduced the need for placement of an RVAD.⁴⁵ In patients with marked elevation of central venous pressure, multiorgan failure, and severe RV dysfunction with low pulmonary artery pressures, early biventricular support may be indicated.⁴⁵ Posttransplantation survival among the patient requiring prolonged RV support (mechanical or otherwise) tends to be lower when compared with those with preserved RV function following an LVAD implantation.²⁰

Intracranial Bleeding and Thromboembolism

Intracranial hemorrhage is one of the most feared complications of MCS. The reported rates of hemorrhagic stroke are fortunately low and range from 0.01 to 0.08 events per patient-year.⁴⁴

The occurrence of thromboembolic events following MCS is variable and depends on a number of factors including the type of device, duration of support, location and number of cannulation sites, and the presence of prosthetic valves within the heart. Approximately 10% of patients receiving MCS with implantable devices will experience a thromboembolic event or stroke.^{38,39,46} This rate is in the range of 20% for patients on short-term extracorporeal MCS devices.¹ Improvement in the rate of thromboembolic events has come from more aggressive antiplatelet therapy in conjunction with warfarin, improved device design, and more frequent use of LV apical as compared with left atrial cannulation. In patients supported only for short durations, anticoagulation is usually achieved with heparin and antiplatelet therapy. Longer-term support usually requires transition to warfarin and antiplatelet therapy.

Infection

Infections can be device-related (i.e., device endocarditis, percutaneous lead or cannula site infection, pocket infection [infection external to an implanted device]) or nondevice-related (i.e., pneumonia and urinary tract infection). The incidence of early nosocomial device-related infections in patients undergoing MCS is approximately 30% in many series and is related to the acuity of illness in this population of patients.^{38,39,46–51} Patients with persistent or recurrent sepsis, and those patients with device-related infections, tend to have a higher mortality rate than patients without these complications.⁵¹ In patients on long-term MCS, infection remains an important obstacle to successful outcome.⁵¹ Most of these late infections begin in the percutaneous driveline tract and pocket of the device. However, clinical experience has revealed that VAD infection rates can be minimized with attention to infection control guidelines, optimal implantation techniques, meticulous wound care, and the utilization of new continuous-flow rotary pump technology.⁵¹

Risk factors for development of infection present before device insertion include preoperative infection at remote sites (not in the area of implantation), malnutrition, prolonged hospitalization, immobilization, broad-spectrum antibiotic therapy, immunosuppressive medications, mechanical ventilation, and the presence of central venous catheters. The percutaneous lead of the device can be a port of entry for bacterial and fungal pathogens. Intracorporeal device infections can occur within the pumps themselves and on their outer surfaces, which are generally caused by biofilm-forming bacteria and fungi. Device-related infections can sometimes be successfully treated with antibiotic suppression and device exchange or removal. Infections involving the preperitoneal pocket (subfascial space created for device placement) surrounding implantable VADs require more aggressive treatment, including open drainage, debridement, omental translocation, and rerouting of the percutaneous lead through a fresh exit site. However, patients who are device-dependent and awaiting transplantation generally cannot tolerate device removal as a therapeutic option to eradicate the infection. Antibiotic suppression and transplantation remain the only chance for cure of device-related infections in these instances. These infections do not generally preclude heart transplantation. However, transplant survival is adversely influenced by the presence of MCS infections at the time of heart transplant and MCS explant.

Device Malfunction and Thrombosis

As with any mechanical device, malfunction is an anticipated occurrence. The types and severity of device malfunctions vary with each of the devices. Many devices have built-in backup systems that, in the event of catastrophic device failure, provide support to the patient. In some instances, patients supported by a VAD have enough residual LV function remaining to help sustain them until corrective measures can be taken in the event of complete device failure. New technology incorporating continuous-flow rotary pump design present new challenges to device malfunction. These devices do not contain valves to direct the flow of blood, and stoppage of the pump is associated with significant regurgitation of blood through the device resulting in significant LV distension. This phenomenon is similar to the development of acute aortic insufficiency. Fortunately, the reported frequency of this event is low.^{32,33} Device malfunctions in TAHs are more problematic as there is no native heart to provide hemodynamic support in the event of a total device failure. Stringent quality control measures in fabrication and testing and very low mechanical failure rates are, therefore, even more essential with TAHs.

Pump thrombosis is potentially a catastrophic complication of VAD therapy. The variability in clinical presentation makes it a challenging diagnosis. It occurs both early and late after VAD implantation and may manifest itself with increased pump power, decreased device flow with heart failure, and hemolysis with hemoglobinuria or with embolic event (peripheral or neurologic). With echocardiography examination, worsening mitral regurgitation, left ventricular distention or persistent opening of the aortic valve, or inability to decompress the LV with increasing degrees of LVAD pump speeds may aid in confirming the diagnosis. Serum lactate dehydrogenase level seems to have established itself as the primary biochemical marker of hemolysis in this clinical context. The rates of device thrombosis initially reported at 2% to 4% in the pivotal Heartmate II trials may underrepresent the true incidence of this complication in durable VADs.^{38,39,49} A recent report looking at incidence of pump thrombosis at three high-volume centers suggests an abrupt increase in the recent years and occurring at the rates of 4.7%, 7.5%, and 12.3% at 6, 12, and 24 months, respectively.⁵²⁻⁵⁴ Clinically suspected thrombosis can be managed medically by intravenous anticoagulation, antiplatelet agents, or thrombolytics in some cases. Surgical treatment by pump explantation with either pump replacement or urgent heart transplantation is generally required in most circumstances.

Interagency Registry for Mechanically Assisted Circulatory Support

8 The Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) database, sponsored by the United States National Heart, Lung and Blood Institute (NHLBI), is a registry for patients who receive implantable or “durable” MCS devices that are approved by the FDA.¹³ The INTERMACS registry represents one of the largest available data repositories for the study of durable or long-term MCS device outcomes. The most recent published data analysis of MCS outcomes for VAD therapy reviews the nearly 6 years of data entry into the registry with more than 10,000 patients.¹³ It includes data on a variety of pulsatile and continuous flow rotary pumps and TAHs. Survival with LVAD support alone at 1 and 2 years continues to be 80% and 70%, respectively, and is significantly worse for those patients requiring BiVAD or TAH support¹³ (Figs. 84-5 to 84-7). MCS as DT strategy continues to represent the majority of implants and the proportion of patients treated in this fashion has increased

from 14.7% in 2006–2007 to 41.6% in 2011–2103¹³ (Table 84-1) At the same time, the proportion of patients listed for transplantation decreased significantly: from 42.4% to 21.7%. Patients undergoing implantation of an MCS device in the presence of cardiogenic shock (i.e., INTERMACS levels 1 and 2) had worse outcomes compared with device implantation in patients with more stable forms of advanced heart failure (INTERMACS levels 3 through 7)¹³ (Fig. 56-7; Table 84-2). These observations highlight the importance of proper patient selection and timing of initiation of MCS therapy on outcomes. Patients with significant organ dysfunction at the time of MCS device implant, accompanied by a greater degree of hemodynamic compromise, have a significantly higher risk of requiring BiVAD support, higher risk of major adverse events, and significantly higher risk of death during VAD support.

Figure 84-5. Actuarial survival for primary device implant, stratified by device type. Error bars indicate $\pm$ 1 SE. Patients are censored at transplant and recovery. CF, continuous flow; LVAD, left ventricular assist device; PF, pulsatile flow; TAH, total artificial heart. (From Kirklin JK, Naftel DC, Pagani FD, et al. Sixth INTERMACS annual report: a 10,000-patient database. *J Heart Lung Transplant* 2014;33:1304–1311, with permission.)

Error bars indicate $\pm$ 1 SE. (From Kirklin JK, Naftel DC, Pagani FD, et al. Sixth INTERMACS annual report: a 10,000-patient database. *J Heart Lung Transplant* 2014;33:1304–1311, with permission.)

WEANING PATIENTS FROM MCS

Weaning From Short-Term MCS

A number of factors are considered when weaning patients from MCS. Major cardiac abnormalities not addressed before or during support render the chances of weaning from MCS negligible. Optimization of volume status, afterload, cardiac rhythm, and degree of inotropic support as well as exclusion of obvious surgical pathology, such as tamponade, is paramount before attempting separation from MCS. In addition, extracardiac causes, such as pulmonary edema, elevated pulmonary vascular resistance, acute respiratory distress syndrome (ARDS), and pneumonia, may worsen right ventricular function and prevent successful weaning from MCS.

Once a patient's status has been optimized, weaning from MCS aided with echocardiographic monitoring is preferred. As device flows are reduced, transesophageal echocardiogram provides information on ventricular filling and performance and valve function. If patients maintain satisfactory hemodynamics with reduction of pump flow, they can be considered for weaning. In the setting of biventricular support, it is important that device flows on the right side be reduced before lowering left-sided device flows. This prevents pulmonary edema in the event of inadequate LV function. As device flows are reduced, native heart function begins to support the circulation. When weaning from MCS is not possible, patients should be evaluated for heart transplantation and/or bridged to a long-term MCS device.

Figure 84-7. Survival analysis for patients on mechanical circulatory support by INTERMACS Profile. Error bars indicate ± 1 SE. See Table 84-2 for a description of INTERMACS Profiles. (From Kirklin JK, Naftel DC, Pagani FD, et al. Sixth INTERMACS annual report: a 10,000-patient database. *J Heart Lung Transplant* 2014;33:1304–1311, with permission.)

Table 84-1 MCS Device Implants by Implant Era and Indications for MCS Device Implantation in the INTERMACS Registry

Device Strategy at the Time of Implant	Implant Date Era						Total	
	2006–2007		2008–2010		2011–2013			
	<i>n</i>	%	<i>n</i>	%	<i>n</i>	%	<i>n</i>	%

Weaning From Long-Term MCS

Anecdotal observations from the cumulative experience with long-term MCS for BTT and recent small clinical studies have demonstrated that long-term MCS, associated with sustained mechanical unloading of the LV, can improve myocardial function even in those patients thought to have irreversible, dilated cardiomyopathies.^{55–57} Several studies have demonstrated that long-term MCS can restore ventricular geometry, improve myocyte function, orientation, and size, reduce myocyte apoptosis, reduce myocardial cytokine gene and protein expression, reverse abnormal neurohormonal patterns associated with advanced heart failure, and improve myocardial mitochondrial function.^{55–57} These observations have led clinicians to consider MCS alone, or in conjunction with other future possible therapies (novel medications; gene therapy; myocyte or stem cell implantation), as a potential modality to reverse end-stage cardiomyopathy. Whether these observation hold under future rigorous experimental scrutiny remains unknown at this time.

MCS DEVICES

The devices currently approved by the FDA are broadly grouped into two categories on the basis of their durability and the intended length of support and use.

Devices Intended for Short-Term MCS (Temporary Devices)

IABP

Since its first reported clinical use by Kantrowitz in 1968, the IABP has become the most frequently utilized MCS device (Fig. 84-8).⁵⁸ The IABP can be inserted percutaneously and is positioned within the descending thoracic aorta. It augments ventricular performance and cardiac output increasing diastolic coronary blood flow, decreasing myocardial oxygen consumption, and reducing left ventricular afterload. Inflation of the balloon during diastole increases diastolic pressure and coronary blood flow and deflation of the balloon during systole reduces arterial afterload facilitating LV ejection. Although the IABP has been the mainstay of circulatory support for decades, the utility of IABP in cardiogenic shock complicating acute myocardial infarction was recently challenged by the results of the SHOCK-IABP Trial.⁵⁹ This prospective study randomized 600 patients to IABP counterpulsation or no IABP counterpulsation in addition to revascularization and optimal medical therapy. The study revealed no difference in 30-day mortality, length of stay in the intensive care unit, serum lactate level, incidence of renal failure, or duration of catecholamine therapy.⁵⁹ Complications from the use of the IABP include leg ischemia, balloon rupture, infection, bleeding, false aneurysm formation, femoral neuropathy, vessel perforation with hemorrhage, and aortic dissection. Female gender, peripheral vascular disease, diabetes, smoking, advanced age, obesity, and cardiogenic shock are predisposing factors for tissue malperfusion and limb ischemia. The IABP has several disadvantages. The augmentation of cardiac output is generally small (approximately 15% in optimal circumstances) when compared with that of conventional VADs and mobilization of the patient is very limited with percutaneous approaches through the femoral arteries. The use of the axillary or subclavian arteries with direct operative placement or percutaneous insertion may permit some degrees of patient mobility.

Extracorporeal Life Support

Extracorporeal life support, traditionally referred to as “extracorporeal membrane oxygenation” is a temporary form of MCS that provides circulatory assistance while allowing for both oxygenation and carbon dioxide removal from blood.^{60–63} The ECLS circuit is conceptually similar in concept to CPB; however, the inclusion of membrane or hollow-fiber oxygenators has allowed for safe application for extended periods of time (usually days to weeks). Since the first successful use of prolonged ECLS, reported by Hill in 1972,⁶³ ECLS has been used in a variety of both pediatric and adult clinical settings, including respiratory support, postcardiotomy support, and as a bridge to an LVAD or heart and/or lung transplantation.⁶⁴

ECLS Achieves Circulatory by Unloading the RV. The blood is drained from the venous circulation, oxygenated it, and returned to the arterial circulation. Although it does reduce LV preload by decreasing the pulmonary venous return, ECLS does not directly unload the LV. In patients with severe LV dysfunction, the use of an IABP and catecholamines helps reduce LV afterload and improves myocardial contractility, thus preventing blood stasis and thrombus formation within the LV. If LV function is so severely reduced that there is essentially no ejection, an atrial septostomy or insertion of a left-atrial venting system can be performed to relieve LV distention. Maintenance of some degree of pulmonary blood flow during ECLS is important in preventing pulmonary artery and vein thrombosis, while minimal ventilatory settings ensure that the oxygen saturation of the blood ejected from the left ventricle is adequate. Venovenous ECLS, unlike venoarterial ECLS, maintains flow through the heart and is used solely for pulmonary support.

Table 84-2 INTERMACS Profiles: Description of Heart Failure Symptoms and Hemodynamic Status at the Time of MCS Device Implantation and Including the Time Frame for Intervention

INTERMACS Profile Descriptions	Time Frame for Intervention
Profile 1: Critical cardiogenic shock Patients with life-threatening hypotension despite rapidly escalating inotropic support, critical organ hypoperfusion, often confirmed by worsening acidosis and/or lactate levels. <i>"Crash or burn."</i>	Definitive intervention needed within hours
Profile 2: Progressive decline Patients with declining function despite intravenous inotropic support may be manifested by worsening renal function, nutritional deprivation, inability to restore volume balance. <i>"Sliding on inotropes."</i> Also describes declining status in patients unable to tolerate inotropic therapy.	Definitive intervention needed within few days
Profile 3: Stable but inotrope dependent Patients with stable blood pressure, organ function, nutrition, and symptoms on continuous intravenous inotropic support (or a temporary circulatory support device or both), but demonstrating repeated failure to wean from support due to recurrent symptomatic hypotension or renal dysfunction. <i>"Dependent stability."</i>	Definitive intervention elective over a period of weeks to few months
Profile 4: Resting symptoms Patients can be stabilized close to normal volume status but experience daily symptoms of congestion at rest or during ADLs. Doses of diuretics generally fluctuate at very high levels. More intensive management and surveillance strategies should be considered, which may in some cases reveal poor compliance that would compromise outcomes with any therapy. Some patients may shuffle between 4 and 5.	Definitive intervention elective over period of weeks to few months
Profile 5: Exertion intolerant Comfortable at rest and with ADLs but unable to engage in any other activity, living predominantly within the house. Patients are comfortable at rest without congestive symptoms, but may have underlying refractory elevated volume status, often with renal dysfunction. If underlying nutritional status and organ function are marginal, patient may be more at risk with INTERMACS 4, and require definitive intervention.	Variable urgency, depends upon maintenance of nutrition, organ function, and activity
Profile 6: Exertion limited Patients without evidence of fluid overload is comfortable at rest, and with ADLs and minor activities outside the home but fatigues after the first few minutes of any meaningful activity. Attribution to cardiac limitation requires careful measurement of peak oxygen consumption, in some cases with hemodynamic monitoring to confirm severity of cardiac impairment. <i>"Walking wounded."</i>	Variable, depends upon maintenance of nutrition, organ function, and activity level
Profile 7: Advanced NYHA III A placeholder for more precise specification in future, this level included patients who are without current or recent episodes of unstable fluid balance, living comfortably with meaningful activity limited to mild physical exertion.	Transplantation or circulatory support may not currently be indicated
Modifiers for profiles	Possible profiles to modify
TCS: Temporary Circulatory Support can modify only patients in hospital (other devices would be INTERMACS devices). Includes IABP, ECMO, TandemHeart, Levitronix, BVS 5000 or AB 5000, Impella	1, 2, 3 in hospital
A – Arrhythmia: can modify any profile. Recurrent ventricular tachyarrhythmias that have recently contributed substantially to clinical compromise. This includes frequent ICD shock or requirement for external defibrillator, usually more than twice weekly.	Any profile
FF: Frequent Flyer can modify only outpatients, designating a patient requiring frequent emergency visits or hospitalizations for diuretics, ultrafiltration, or temporary intravenous vasoactive therapy.	3 if at home, 4, 5, 6. A frequent flyer would rarely be profile 7

Current ECLS circuits are typically composed of a centrifugal pump with either a hollow fiber or membrane oxygenator, oxygen blender, pump console, heat exchanger, and pump cart. A roller pump is used by some centers. Cannulation technique for ECLS is extremely variable and depends on the clinical situation and the nature of support required. Percutaneous cannulation of the femoral vein and artery allows for rapid initiation of MCS in cases of acute cardiac and/or respiratory arrest. In less urgent situations, cut-down on the internal jugular and carotid artery or respective femoral vessels can be performed. In cases of postcardiotomy failure in the operating room, venous access can be obtained by insertion of cannula in the right atrium and arterial outflow obtained by cannulation of the ascending aorta. Even though many ECLS perfusion systems are available, new portable ECMO systems such as CardioHelp (Maquet GmbH and Company, Rastatt, Germany) have now attained the FDA approval and may find a useful role in emergency situations due to the relative ease of implantation and initiation.

Figure 84-8. Intra-aortic balloon pump. **A:** Aortic pressure tracing during intra-aortic balloon pump support. Balloon counterpulsation is occurring after every other heartbeat (1:2 counterpulsation). With correct timing, balloon inflation (IP) begins immediately after aortic valve closure, signaled by the dicrotic notch of the arterial waveform. Compared with unassisted ejection, the pump augments diastolic blood flow by increasing peak aortic pressure during diastole. Balloon deflation before systole decreases ventricular afterload, with lower aortic end-diastolic pressure and lower peak systolic pressure. **B:** Console for the intra-aortic balloon pump. **C:** Catheter-mounted balloon is positioned within the thoracic aorta through a percutaneous or surgical approach via the femoral artery. Numerous large clinical series have reported successful use of ECLS for cardiac and/or respiratory support in adult, pediatric, and neonatal patients. In the largest series reported to date, Gray and colleagues⁶⁴ at the University of Michigan reported on the outcome of 2,000 patients supported with ECLS from 1973 through 2010. Of the 2,000 patients, 74% were weaned from ECLS and 64% survived to hospital discharge. In patients with respiratory failure, survival to hospital discharge was 84% in 799 neonates, 76% in 239 children, and 50% in 353 adults. Survival in patients with cardiac failure was 45% in 361 children and 38% in 119 adults. ECLS during extracorporeal cardiopulmonary resuscitation was performed in 129 patients, with 41% surviving to discharge. Survival decreased from 74% to 55% between the first and second 1,000 patients. The most common complication was bleeding at sites other than the head, with an incidence of 39%, and the least frequent complication was pump malfunction, with a 2% incidence. Intracranial bleeding or infarction occurred in 8% of patients, with a 43% survival rate.

Venovenous ECLS was the preferred method of respiratory support since 1988. For patients with cardiac failure, survival in adult patients was improved by utilizing ECLS as a bridge to longer-term implantable devices in patients who did not demonstrate early recovery of myocardial function.^{65–67} Conversely, the availability of long-term implantable devices has extended the use of ECLS in situations where recovery of myocardial function is unlikely.^{65–67}

Percutaneous Short-Term MCS Devices

The 2015 SCAI/ACC/HFSA/STA clinical expert consensus statement endorses the use of percutaneous MCS in carefully selected patients with severe hemodynamic compromise in a variety of clinical scenarios, including complications of acute MI, severe heart failure in the setting of nonischemic cardiomyopathy, acute allograft rejection, posttransplant RV failure, inability to separate from CPB after cardiac surgery, refractory arrhythmia, and prophylactic use during high-risk coronary interventions.¹ The choice of the device depends on the clinical setting, the ease of implantation, the hemodynamic effects of the device, and the goals of therapy. Expert operators may choose percutaneous LVAD systems over IABP to minimize pressor use and myocardial oxygen demand and improve systemic perfusion while substantially decompressing the dysfunctional ventricle and effectively augmenting the cardiac output and tissue perfusion. It is important to note, however, that the extent of clinical data

pertaining to the effectiveness and safety of these devices is still limited. In addition, the cost of the devices and the operating costs substantially exceed those of the IABP.

The *Tandem Heart pVAD* (Cardiac Assist Technologies, Inc., Pittsburgh, PA) is currently the only available percutaneous left atrial-to-femoral artery VAD⁶⁸ (Fig. 84-9). This dual-chamber, low-speed continuous-flow, centrifugal device bypasses the LV by pumping blood extracorporeally from the left atrium to the femoral arterial system via a catheter placed across the atrial septum into the left atrium. It is a dual-chamber pump composed of an upper and a lower housing assembly, providing a conduit for inflow and outflow of blood and communication with the controller, respectively. The controller ensures hydrodynamic bearing support of the LVAD impeller and rotation at 3,000 to 7,500 rpm, as well as its cooling and delivery of local anticoagulation. The controller is a microprocessor-based electromechanical drive operated on AC current or internal batteries.

Figure 84-9. A: The Tandem Heart pVAD centrifugal pump (CardiacAssist Corporation, Pittsburgh, PA). The TandemHeart pVAD is an extracorporeal, continuous-flow rotary pump with centrifugal design providing temporary mechanical circulatory support to the left ventricle (left atrium to femoral artery). The TandemHeart pVAD utilizes a bearing design in the pump for impeller positioning and rotation. B: Schematic representation of the cannulation of the femoral artery and femoral vein with the transseptal placement of the inflow catheter within the left atrium from the femoral vein. The centrifugal pump of the Tandem Heart pVAD is secured to the patient's right thigh. (Photographs courtesy of CardiacAssist Corporation, Pittsburgh, PA.)

Implantation of the device is performed percutaneously via the right femoral vein. A standard Brockenbrough catheter inserted into the superior vena cava allows for interatrial septostomy, through which a venous inflow cannula is introduced. An arterial perfusion catheter, ranging in size from 15F to 19F, is inserted percutaneously into the right femoral artery.

Hemodynamic effects of this device are based on the parallel flow contribution to the aorta of both the device and the LV itself. This results in reduction of LV preload, myocardial oxygen consumption, filling pressures, and ventricular wall stress.⁶⁹ Depending on the size of the arterial cannula, the device flow varies from 3.5 to 5.0 L/min.

In a randomized comparison of IABP with the Tandem Heart pVAD, Thiele and colleagues⁶⁸ reported a more effective improvement in cardiac power index as well as other hemodynamic and metabolic variables with the Tandem Heart pVAD compared with the IABP. Even though 30-day mortality rate was similar between the two groups, complications like severe bleeding and limb ischemia were encountered more frequently during VAD support.⁶⁸ The Tandem Heart pVAD is FDA-approved for temporary MCS for cardiogenic shock in patients refractory to optimal medical therapy and IABP.

Impella LVAD (Abiomed Corporation, Danvers, MA) is a continuous flow rotary pump with axial design that propels blood from the LV across the aortic valve and into the ascending aorta^{70,71} (Fig. 84-10). It is currently available in three delivery platforms for LV support including a 12F (Impella LP 2.5), 21F

(Impella LP 5.0), and 14F (Impella CP) system and Impella RP, a system uniquely designed for RV support. While the Impella 2.5 and 5.0 provide maximal flow rates of 2.5 and 5.0 L/min, respectively, the Impella CP achieves maximal flows of approximately 4 L/min despite its smaller platform. The two smaller devices can be inserted percutaneously, while the larger device may require surgical cut-down. The preferred site of introduction is the femoral artery; however, the devices have been introduced via the axillary artery or directly into the aorta. The LVAD is positioned across the aortic valve with the inlet port below and outlet above the aortic valve.

The hemodynamic effects of Impella devices are based on LV unloading and augmentation of forward flow. This reduces myocardial oxygen consumption, improves mean arterial blood pressure, and reduces pulmonary capillary wedge pressure.⁷² Similar to the TandemHeart, proper function of the Impella LVAD requires adequate RV function or RV support to provide sufficient preload for the devices. In a prospective, randomized clinical trial comparing the Impella LP2.5 to IABP, cardiac index was significantly increased in patients with the LP2.5 compared with patients supported with an IABP. Overall mortality rate at 30 days was similar in both groups.⁷⁰

The Impella RP (Fig. 84-10) is a novel RVAD designed using the Impella system but adapted for right ventricular support. The pump supports the pulmonary circulation with intent to reduce right ventricular work and potentially recover right ventricular contractility. The pump is inserted percutaneously via the femoral vein and capable of delivering up to 4 L/min of blood flow from the right atrium to the pulmonary artery.

Figure 84-10. The Impella left ventricular assist device (Abiomed Inc., Danvers, MA). **A:** Diagram demonstrating positioning of the device across the aortic valve. Device inflow is within the left ventricle and device outflow is above the aortic valve. **B:** Impella 5.0. **C:** Impella RP. (Photographs courtesy of Abiomed Inc., Danvers, MA.)

The *CentriMag VAD* (Levitronix LLC; Waltham, MA) is an extracorporeal, continuous flow rotary pump composed of a centrifugal blood pump, a motor, a console, a flow probe, and a circuit^{73,74} (Fig. 84-11). The device is based on a magnetically levitated “bearingless motor” design. The rotor located within the upper pump housing is magnetically coupled to the lower motor housing to produce rotor levitation and spin which combines the drive, the magnetic bearing and the rotor function into a single unit. The motor generates the magnetic bearing force that levitates the rotor into the pump housing while also generating the torque necessary to produce the unidirectional flow. This device can produce flows of up to 10 L/min under normal physiologic conditions, with a priming volume of 31 mL. Both left and right ventricular systems exist and have been used as a BTR, BTT, or bridge to a long-term MCS. Single-center reports have demonstrated successful use of both left and right ventricular Centri-Mag systems as a BTT,

BTR, or bridge to a long-term implantable MCS.^{73,74} The Centri-Mag system can be utilized in series with an oxygenator as an ECLS system.

Implantable Devices Intended for Long-Term MCS for Out-of-Hospital Use (BTT and DT Indications)

Historical Perspective

The majority of patients receiving long-term MCS in the 1990s and early 2000s were supported by devices engineered with pulsatile, volume displacement designs. These first-generation devices, now obsolete in clinical practice, were engineered with an internal reservoir chamber and inflow and outflow valves that permit cyclic filling and emptying of the device with pump actuation elicited by either pneumatic or electrical drive systems.

Extended periods of MCS highlighted limitations in the design of pulsatile, volume displacement pumps that included a large pump size restricting mobility, requirement for extensive surgical dissection for implant leading to bleeding and infection complications, a large body habitus of the recipient limiting options for device therapy for women or smaller patients, the presence of a large-diameter percutaneous lead for venting air, and audible pump operation. A critical limitation of these devices was the high incidence of reoperation for device exchange for device malfunction.⁷⁵ To overcome these limitations, newer device designs incorporating continuous-flow rotary pump technology with an axial or centrifugal blood path represent the next generation of devices for long-term MCS therapy.

Implantable, Continuous-Flow Rotary MCS Devices

9 Implantable, continuous-flow, rotary pumps with axial or centrifugal blood flow design represent a new generation of implantable VAD technology that have now completely replaced pulsatile devices for long-term MCS indications.^{46–50,76} Rotary pumps have an internal impeller within the blood flow path that is suspended by contact bearings or in more recent cases by hydrodynamic or magnetic forces. Rotary pumps offer several advantages over pulsatile, volume displacement pumps. These advantages include smaller size, fewer moving parts, durability, absence of valves to direct blood flow, smaller blood contacting surfaces, and reduced energy requirements. Blood flow is accomplished by the spinning of an internal rotor at high speed that imparts significant kinetic energy to the blood. The spinning of the rotor is accomplished by actuating an electrical current and magnetic field around the rotor that contains internal magnets. Blood flow from left ventricle to the aorta occurs continuously during the systolic and diastolic phases of the cardiac cycle. Although blood flow is continuous during the cardiac cycle, phasic changes in the flow of blood occur during the cardiac cycle due to changes in ventricular pressure and aortic afterload. These phasic changes in blood flow impart a diminished pulsatility to the aortic waveform. The ability to design smaller pumps using rotary pump technology is a result of the elimination of a large blood chamber necessary with pulsatile systems. An additional important feature of these pumps is the lack of need for a compliance chamber. This feature alleviates the problem of internal compensation that is associated with conventional pulsatile pumps that, to date, has significantly hindered total internalization.

Figure 84-11. The CentriMag VAD. The CentriMag VAD is an extracorporeal, continuous-flow rotary pump with centrifugal design utilized for temporary mechanical circulatory support. The CentriMag can provide univentricular or biventricular support. **A:** The CentriMag console (background) and pump/motor (foreground). **B:** Schematic representation of the CentriMag pump. The rotor located within the upper pump housing is magnetically coupled to the lower motor housing to produce rotor levitation and spin. (Photograph courtesy of Levitronix LLC, Waltham, MA.)

Rotary pump designs incorporating pump technology with an axial blood path have accumulated significant human clinical experience. Reports from clinical trials with rotary pumps have demonstrated efficacy in providing hemodynamic support, a favorable risk to benefit assessment, and improvement in mechanical performance.^{46–50,76} Furthermore, the human experience with the newer generation of rotary pumps with axial or centrifugal design has established the long-term safety of MCS with minimal pulse pressure.^{77,78} Results from clinical studies have demonstrated early improvement followed by long-term stability of renal and hepatic function and no adverse effects on neurocognitive performance.^{46–50} These improvements in device technology with continuous-flow rotary pumps have increased the acceptance and adoption of LVAD therapy for long-term MCS indications.

Implantable, Continuous-Flow MCS Devices (Rotary Pumps with Axial Flow Design)

HeartMate II. The HeartMate II LVAD (Thoratec Corporation, Pleasanton, CA)^{38,39,47–50} (Fig. 84-12) is continuous-flow rotary pump with axial design and mechanical bearing support of the internal impeller. The sealed inflow conduit of the pump is attached to the apex of the LV and the pump sealed outflow graft is connected to the ascending aorta, creating a circuit parallel to the native circulation. A magnet within the pump's rotor assembly is rotated by the electromotive force generated by the motor itself. This rotation is the driving force propelling the blood from the left ventricle through the pump into the ascending aorta. The flow generated by the pump depends on the rotational speed of the rotor as well as the pressure difference between the inlet and outlet of the pump. The internal pump surfaces are lined with smooth polished titanium, while the sealed inflow conduit and outflow elbow have a textured titanium microsphere surface. The percutaneous lead (drive-line) transmits commands and power from the external System Controller and power source to the LVAD itself. The system can be powered by portable batteries.

The HeartMate II was approved for BTT therapy in 2008 and for DT in 2010, following two pivotal safety and efficacy trials, and is the most utilized and studied LVAD pump to date. In a prospective, multicenter, controlled study of HeartMate II as BTT, 133 patients with end-stage heart failure while on the waiting list for heart transplantation underwent implantation of the LVAD. The primary end point (the proportions of patients who had undergone transplantation, had cardiac recovery, or had ongoing mechanical support while remaining eligible for transplantation) was evaluated at 180 days postimplantation. Three quarters of the patients reached the primary end point. Of these 100 patients, only one recovered myocardial function and had the VAD explanted. The rest were either transplanted (56 patients) or continued requiring LVAD support (43 patients). Overall actuarial survival for patients continuing to receive LVAD support was 89% at 1 month, 75% at 6 months, and 68% at 12 months.⁴⁹ A follow-up report of the initial 133 patients in addition to 148 patients entered through the Continuous Access Protocol³⁸ reveals that at 18-month follow-up, 157 patients (55.8%) had received a heart transplant, 58 patients (20.6%) remained alive with ongoing LVAD support, 56 patients (19.9%) died, 7 patients (2.5%) recovered cardiac function and underwent device explantation, and 3 patients (1%) were withdrawn from the study after device explantation and exchange for another type of LVAD. Overall survival rate for the patients who continued on LVAD support was 82% (95% confidence interval [CI]: 77% to 87%) at 6 months, 73% (95% CI: 66% to 80%) at 1 year, and 72% (95% CI: 65% to 79%) at 18 months. The most common adverse effects were bleeding, stroke, infection, and neurocognitive dysfunction, while sepsis and stroke were the primary causes of mortality. The post-FDA-approval study of the HeartMate II for Bridge to Transplant indication reported comparable results with HeartMate II in a commercial setting to those of other available devices for the same indication. The cohort of 338 patients was followed for at least 12 months or until death or transplantation. Both the 30-day mortality rate and the in-hospital mortality rate were significantly lower among the LVAD patients (4% vs. 11%, and 6% vs. 15%, respectively). Patients supported with the HeartMate spent less time in the hospital, were more likely to be discharged home, and reported better quality of life.⁴⁷

Figure 84-12. A: The HeartMate II LVAD (Thoratec Corporation, Pleasanton, CA) is an implantable, continuous-flow rotary left ventricular assist device with axial design intended for long-term mechanical circulatory support for bridge to transplantation or destination therapy. Schematic drawing showing internal rotor, stators, and bearings and external motor coils. (Drawing courtesy of Thoratec Corporation, Pleasanton, CA.) B: Schematic representation of the HeartMate II in the preperitoneal position with associated percutaneous lead, external controller, and power source (batteries).

The randomized, prospective, multicenter HeartMate II Pivotal Trial for DT enrolled 200 patients who were not eligible for cardiac transplantation. They were assigned in a 2:1 ratio to receive either the HeartMate II or HeartMate XVE and followed for at least 2 years or until death, transplantation, or device explantation. The primary composite end-point was reached in more patients in the study group than in the control group (46% vs. 11%; hazard ratio, 0.38; 95% CI, 0.27 to 0.54; $P < 0.001$). The HeartMate II population experienced higher actuarial survival rates and lower rates of pump replacement for malfunction and thrombosis, infection, renal failure, RV failure, respiratory failure, and arrhythmias. Both groups experienced significant improvement in functional capacity and overall quality of life.^{39,50} The post-FDA-approval study supported the original pivotal clinical trial findings regarding the efficacy and risk profile of the HeartMate II LVAD. Survival was best in patients who were not inotrope-dependent (INTERMACS profiles 4-7).⁴⁸

Jarvik 2000. The Jarvik 2000 (Jarvik Heart, Inc., New York, NY) is a continuous-flow rotary pump with axial blood flow implanted intraventricularly⁷⁹⁻⁸¹ (Fig. 84-13). This pump is inserted through a sewing cuff attached to the apex of the left ventricle. The outflow orifice of the pump is attached to a Dacron graft for anastomosis to the descending or ascending thoracic aorta. The current adult version of the Jarvik 2000 measures 2.5 cm in diameter by 5.5 cm in length, with a weight of 85 g and a displacement volume of 25 mL. The adult pump functions at a speed of 8,000 to 12,000 rpm, achieving blood flows up to 8 L/min. Percutaneous power is delivered from external batteries via a controller unit. Internal electrical wires are brought via the left pleural cavity to the apex of the chest and then subcutaneously across the neck to the base of the skull, where a percutaneous titanium pedestal transmits fine electrical wires through the skin of the scalp. The early clinical studies suggest that this LVAD system can be used safely in selected patients to provide support until transplant or as DT.⁸⁰⁻⁸² In 2012, the FDA approved the Jarvik 2000 to undergo clinical evaluation for DT.

Figure 84-13. The Jarvik 2000 (Jarvik Heart Corporation, New York, NY) is an implantable, continuous-flow rotary left ventricular assist device with axial design intended for long-term mechanical circulatory support for bridge to transplant or destination therapy. Schematic representation of the placement of the Jarvik 2000 within the left ventricle.

Implantable, Continuous-Flow MCS Devices (Rotary Pumps With Centrifugal Flow Design)

Although significant improvements in pump design have occurred with continuous flow rotary pumps, the use of a mechanical bearing support for the internal impeller, typical of most axial designs, has potential limitations. The presence of rotor-suspending contact bearings in the blood path represents a potential point of frictional wear that can result in device failure and subsequent need for device exchange.^{76,82,83} Rotary pumps with axial design with bearing support still demonstrate the potential for thrombus formation on the device rotor and bearing interface due to the presence of stasis and incomplete bearing “wash” of the bearings and formation of heat from frictional at the bearing surfaces.^{53,54} The presence of stators to suspend and redirect blood flow also represents an obstruction within the blood flow path. Clinical studies have also documented reduced but persistent risk of thromboembolic stroke as well as hemorrhagic complications owing to the required long-term anticoagulation therapy.^{44,46–50,53,54} An additional potential limitation of axial designs in general is related to their hydrodynamic performance. To observe changes in pump flow at a fixed rotor speed, significant changes in pressure across the inlet and outlet orifices of the pump must occur.⁸⁴ This relative degree of insensitivity of the hydrodynamic performance of the pump or “steep” pressure–flow relationship can result in left ventricular collapse and “suction” when filling pressures are abruptly reduced as in the case of a sudden onset of a ventricular arrhythmia, or result in elevated filling pressures with dyspnea when return to the left atrium is abruptly increased, as with exercise. Left ventricular collapse or “suction” events can, by itself, precipitate serious ventricular arrhythmias,⁸⁵ while the inability to significantly increase pump flow with exercise may limit exercise performance in patients with axial pumps.

Implantable continuous flow rotary pumps with centrifugal flow design represent an alternative design. These devices provide continuous flow at rotational speeds that are much slower, about 2,000 to 4,000 compared with 8,000 to 15,000 rpm observed for pumps with axial flow design. The same general advantages and disadvantages of design features that apply to rotary pumps with axial flow design apply to centrifugal flow design. The major feature current centrifugal designs have is the elimination of the mechanical bearing support of the internal rotor. Current designs achieve impeller rotation and levitation with magnetic or hydrodynamic (fluid) forces eliminating the need for bearings with subsequent problems associated with bearing wear. These designs have a potential for very long durability^{46,77,82,86,87} (Fig. 84-14). Impeller rotation to elicit blood flow is achieved through magnetic coupling to the pump motor. Levitation systems suspend the moving impeller within the blood field without any mechanical contact, thus eliminating frictional wear and reducing heat generation that would normally take place at the contact surface with a contact bearing design. These levitation forces may be achieved through magnetic or hydrodynamic bearing design. Magnetic forces may be passive without the consumption of power (permanent magnet) or active (induction of magnetic field with electricity) in design.^{46,76,82,86,87} Hydrodynamic levitation depends on fluid forces generated by the rotating impeller to levitate the internal impeller. Pump designs can be further distinguished by the

utilization of hydrodynamic levitation only, hydrodynamic levitation working in synergy with magnetic levitation for suspension, or variations of active and/or passive magnetic levitation. Active magnetic levitation of the impeller typically utilizes complex position sensing and control systems that increase requirements for a larger pump size. Hydrodynamic suspension does not utilize position sensors resulting in a less complicated electronic design and ability to miniaturize pump size. The design of any levitation system must be adequate to control the six degrees-of-freedom of movement of the suspended impeller.

Figure 84-14. Schematic representation of a continuous-flow rotary pump utilizing magnetic coupling of the internal impeller for levitation and rotation that obviates the need for bearings in the blood flow path.

Centrifugal pumps typically, although not exclusively, have a more sensitive pressure–flow relationship as compared with rotary pumps with axial design.^{46,76,82,86,87} This greater sensitivity of the pressure-flow relationship in rotary pumps with centrifugal design results in greater changes in flow for any given change in pressure across the inlet and outlet orifices of the pump. This greater pump response to changes in flow may increase the margin of safety from creating suction events and improves pump flow during increases in left atrial return potentially enhancing exercise response.^{76,82,86,87} The improvements in design attributes of rotary pumps with centrifugal design, such as mechanical wear, operation at low flow, and perceived improved potential for hemocompatibility, while still maintaining a manageable size, warrant further clinical investigation. Whether these attributes of rotary pumps with centrifugal design will result in significant improvement in clinical outcomes over that observed with rotary pumps with axial design is not known at this time.

HVAD. The HVAD (HeartWare Corporation, Miami, FL) is a small continuous-flow rotary pump with centrifugal and noncontact bearing design. The unique feature of the HVAD is its small design size^{46,88,89} (Fig. 84-15). It has a displacement volume of 45 cc and weighs 145 g with a flow capacity of up to 10 L/min. The device is small enough to place within the pericardial cavity without the need for dissection and creation of a preperitoneal pocket. The impeller of the HVAD is suspended in place by combination of passive magnetic and hydrodynamic (i.e., fluid) bearing systems. The impeller suspension system uses a passive magnetic bearing for radial stiffness. Axial magnetic preload and hydrodynamic bearings on top of each impeller blade provide axial constraint. The magnetic bearing consists of a stack of rare-earth ring magnets, near the impeller's inside diameter that repel the magnetic force of a similar stack of magnets inside the center post. The axial alignment of the center-post magnet stack is set to provide an axial force that pushes the impeller toward the forward housing (the assembly with the inflow cannula). Physical contact between the housing and the impeller is prevented by a thin blood film generated by the hydrodynamic bearings.

The HVAD is approved for use in the United States for BTT indication and is currently being evaluated in clinical trial for DT. The ADVANCE trial was a prospective, multicenter evaluation of the HVAD for BTT indication in the United States using a comparator group implanted contemporaneously with a commercially available device in the INTERMACS registry.^{46,89} The primary outcome, success, was defined as survival on the originally implanted device, transplantation, or explantation for ventricular recovery at 180 days and was evaluated for both noninferiority and superiority. Secondary outcomes included a comparison of survival between groups and functional and quality-of-life outcomes and adverse events in the investigational device group. A total of 140 patients received the investigational pump, and 499 patients received a commercially available pump implanted contemporaneously. Success occurred in 90.7% of investigational pump patients and 90.1% of controls, establishing the noninferiority of the investigational pump ($P < 0.001$; 15% noninferiority margin). At 6 months,

median 6-minute walk distance improved by 128.5 m, and both disease-specific and global quality-of-life scores improved significantly. Kaplan–Meier survival estimates at 30, 60, 180, and 360 days were 99%, 96%, 94%, and 86%, respectively, for the investigational device group and 97%, 95%, 90%, and 85%, respectively, for the INTERMACS control group. Bleeding, infections and perioperative right-sided heart failure were the most frequent complications. Inotropic support for greater than 14 days was required by 16.4% of patients. Driveline exit site infections and sepsis occurred in 12.1% and 11.4% of recipients, respectively.

HeartMate III. The HeartMate III LVAD (Thoratec Corp, Pleasanton, CA) is a new compact intrapericardial-positioned continuous flow rotary pump with centrifugal design⁸⁶ (Fig. 84-16). The unique feature of the HeartMate III is the full magnetic levitation of the internal rotor. The design differs from currently used devices due to active control of rotation and levitation of the rotor that permits impeller movement further away from the outer housing creating larger gaps for blood flow within the device. The larger gaps may reduce blood component trauma and improve biocompatibility. The HeartMate III is currently under clinical investigation in the United States.

Following the first-in-man implantation at Hannover Medical School in Germany, the device underwent a clinical investigation in Europe and Canada through the Conformité Européenne Mark clinical trial, which enrolled 50 patients with end-stage heart failure. The 6-month follow-up is in progress. The device is under investigation in a clinical trial in the United States, and the enrollment is currently ongoing.

MVAD. The MVAD (HeartWare Inc., Framingham, MA) is a novel continuous axial flow pump, approximately one-third the size of the HVAD (Fig. 84-17).⁹⁰ The contactless impeller suspension technology has a single moving part – the rotor, secured in place by a combination of passive-magnetic and hydrodynamic forces. The device allows for two distinct flow pathways – the primary flow path is through the impeller channels, and the secondary flow path is through the radial gap between the impeller and inner pump housing. The MVAD is to begin clinical evaluation in 2015.

Total Artificial Hearts

Syncardia Total Artificial Heart

The Syncardia TAH-t (SynCardia Systems Corporation, Tucson, AZ) is a pulsatile, volume displacement, TAH⁹¹⁻⁹³ (Fig. 84-18). The rigid polyurethane pump contains a flexible polyurethane diaphragm that separates blood and air chambers. Two mechanical valves located at the inflow and outflow orifices ensure unidirectional blood flow. Compressed air from the external drive console moves the diaphragm upward, pressurizing the blood chamber and causing ejection of blood. The pump has a maximum stroke volume of 70 mL and a maximum flow rate of 15 L/min, although the average flow rate is <8 L/min. Pump rate, duration of systole, and driving pressure can be adjusted to achieve optimal flow conditions. The TAH is surgically implanted in the mediastinal space after the ventricles have been excised, while the atrial cuffs are retained. The pneumatic drivelines are externalized percutaneously and attached to the drive console. Ambulation is facilitated by small portable drive systems and consoles. The Syncardia TAH-t is approved by the FDA for bridge to heart transplant indication. In a recent study, Copeland and colleagues⁹² reported a survival rate of 79% to heart transplantation compared with 46% for the observational arm. One-year posttransplant survival rate was 86%. A newer design incorporating a smaller 50-cc ventricle to facilitate the use in smaller patients is currently in clinical evaluation.

FUTURE DIRECTIONS

Recent rapid technologic advancements and successful clinical applications of MCS have made the future of this field optimistic but uncertain. Areas of continued research include the use of wireless energy transfer to facilitate complete internalization of MCS devices, application of less invasive surgical techniques for device implantation, application of MCS devices for the pediatric population, partial support devices and device designs, and new materials to improve compatibility of the blood-device interface to reduce thromboembolic complications and need for anticoagulation. It is possible that long-term MCS will provide a viable alternative to heart transplantation and medical therapy for patients with advanced heart failure. Because of the technologic advancements, it will be difficult to predict what devices will ultimately prove to be the most efficacious. It is likely that a variety of devices will become available for use, depending on clinical circumstances and patient characteristics.

Chapter 85

Thoracic Aortic Aneurysms and Aortic Dissection

Ravi K. Ghanta and Gorav Ailawadi

Key Points

- 1 The risk of thoracic aneurysm disease increases with age. Thoracic aortic aneurysms in young patients are most likely due to genetic predisposition or familial syndromes.
 - 2 Careful planning by experienced centers is paramount to provide optimal treatment in patients with thoracic aortic aneurysms as the morbidity and mortality for surgical intervention are significant.
 - 3 Open surgical repair remains the mainstay for aortic root, ascending aortic, and aortic arch aneurysms with very acceptable outcomes and low morbidity when performed in centers of excellence.
 - 4 Endovascular techniques for the descending thoracic aorta have become the preferred treatment approach not only for aneurysms, but for dissections and acute traumatic aortic injuries as they often can be performed with less morbidity than that associated with open surgical treatment.
 - 5 Aortic dissection is associated with higher operative morbidity and mortality. Stanford type A aortic dissection mandates emergent operation. Stanford type B aortic dissection may be managed medically if uncomplicated or with endovascular therapy if complicated. Management is evolving with advancements in endovascular techniques.
-

Aortic diseases constitute the 13th leading cause of death in the developed world. Aneurysms can affect the entire aorta, but aneurysms of the thoracic aorta, in particular, are associated with the highest morbidity and mortality (Fig. 85-1). An aortic aneurysm is defined as a dilation of the diameter of at least 50% greater than baseline. *True aortic aneurysms* affect all the layers of the aortic wall – intima, media, and adventitia – and should be distinguished from *false aneurysms (pseudoaneurysms)*, which occur after trauma, surgery, or other injury and only involve the media and adventitia. Although understanding of the pathogenesis of aortic aneurysms is rapidly evolving, degradation of the aortic extracellular matrix proteins, collagen and elastin, and loss of smooth muscle cells are hallmark pathologic findings. In contradistinction to abdominal aortic aneurysms, ascending aneurysms less commonly display manifestations of atherosclerosis or an inflammatory infiltrate.

Thoracic aortic disease is associated with significant risk primarily due to catastrophic rupture or dissection. *Aortic dissections* are intimal tears resulting in blood propagating within the medial layer, leading to true and false lumens of blood flow. False-lumen perfusion can lead to visceral organ malperfusion. Although dissections most commonly occur in aneurysms, dissections can also occur in nonaneurysmal aortas with connective tissue or other aortic wall pathologies. Chronic aortic dissections can also become aneurysmal over time, necessitating intervention. Treatment decisions concerning operative intervention in terms of both timing and extent of resection are often complex and involve multidisciplinary management (Fig. 85-2).

THORACIC AORTIC ANEURYSM

History

The first known description of an arterial aneurysm was by Galen, a Greek physician (A.D. 126–216), who described false aneurysms in injured gladiators.¹ In 1543, Andreas Versalius first described thoracic aortic aneurysms (TAAs). However, it was not until 1895 that an etiology for aneurysms was hypothesized, when Dohle identified syphilitic aortitis.² Aneurysms were originally treated with external or internal ligation via opening the aneurysm. In the later 19th century, Rudolph Matas developed an alternate technique of obtaining proximal and distal control, aneurysm resection, and primary reconstruction.³ These techniques were successful in only a limited number of patients.

The modern surgical treatment of aortic disease began in the 1950s, and the ensuing 20 to 30 years saw the development and failures of many novel techniques.^{4,5} In the early 1950s, the first resection of a descending thoracic aneurysm and replacement with homograft was reported. In 1952, the first excision of a saccular ascending aortic aneurysm without cardiopulmonary bypass was performed by Michael DeBakey and Denton Cooley in Houston.⁶ In 1953, Dubost et al. in Paris and DeBakey and Cooley in Houston reported successful resection and reconstruction of the abdominal aorta with human aortic allograft.^{7,8} The same duo performed a repair of an acute traumatic aortic transection in 1954 through a left thoracotomy with the patient's core temperature reduced to 28°C using surface cooling. They subsequently reported the first successful resection of an ascending aneurysm with cardiopulmonary bypass in 1956 and the first successful arch aneurysm repair in 1957.^{9,10}

Dacron grafts, introduced by DeBakey, largely replaced human allografts, avoiding the need for maintaining large tissue banks and allowing more facilities the ability to treat these patients.^{11,12} In addition, the development and refinement of the cardiopulmonary bypass machine, in large part by John Gibbon at Thomas Jefferson, revolutionized the open surgical repair of thoracic aortic disease. The importance of hypothermia for cerebral protection and specifically the use of hypothermic circulatory arrest (HCA) during aneurysm repair was established by Randy Griepp and colleagues.¹³ Advances in endovascular therapies, led to the development of thoracic aortic stent grafts in 1994 by Michael Dake and colleagues.¹⁴ With these techniques in place, modern surgical practice to treat aortic disease was established.

Figure 85-1. Normal anatomic aortic segments. The aortic root extends from the aortic annulus to the sinotubular junction. The aortic root is the largest diameter section of the aorta when measured at the level of the sinuses of Valsalva. The tubular or ascending segment of the aorta begins at the sinotubular junction and extends to the innominate artery. The aortic arch travels anterior to posterior and the left, giving rise to the head and upper extremity vessels. The descending thoracic aorta begins distal to the left subclavian at the level of the ligamentum arteriosum to the pulmonary artery (PA). The abdominal aorta begins at the level of the diaphragm.

Figure 85-2. A: Sagittal CT scan showing an ascending aortic aneurysm. Computed tomography (B) and angiogram (C) of a patient with a fusiform descending thoracic aortic aneurysm.

Table 85-1 Risk Factors for Thoracic Aortic Aneurysms

Anatomic	Vascular disease
Annulo aortic ectasia	Uncontrolled hypertension
Aortic wall abnormalities	Inflammation
Bicuspid aortic valve	Aortic aneurysm
Chromosomal/genetic	Aortic arteritis
Marfan syndrome	Arthrosclerosis
Ehlers–Danlos syndrome (type 4)	Behçet disease
Noonan syndrome	Giant cell arteritis
Polycystic kidney disease	Ormond disease
Turner syndrome	Syphilis
Congenital	Takayasu arteritis
Aortic arch hypoplasia	Iatrogenic/idiopathic
Aortic coarctation	Aortic cannulation/cross-clamping
Congenital aortic stenosis	Endoluminal transcatheter therapy
Demographic	Graft anastomosis
Age (>60 yrs)	Instrumentation
Lifestyle	Sheehan syndrome
Cocaine	Valvular surgery
Dyslipidemia	
Pregnancy (preeclampsia)	
Smoking	

Prevalence and Classification

Thoracic aneurysms compose 25% of all aortic aneurysms. Approximately 50% of TAAs involve the ascending aorta, 10% the aortic arch, and 40% the descending aorta.¹⁵ True thoracoabdominal aneurysms constitute less than 5% of TAAs.¹⁶ Interestingly, during the first half of the 20th century, thoracic aneurysms were far more common than abdominal aortic aneurysms because of the predominance of infectious (syphilitic) aneurysm in the thoracic aorta. By 1964, however, less than half of aneurysms were in the thorax, primarily as a result of the decline in the incidence of syphilis.¹⁷

The true incidence and prevalence of TAAs is likely underreported. In a Swedish autopsy study, the prevalence of TAAs was reported as 489 per 100,000 men and 437 per 100,000 women.¹⁶ Stratified by age, 65-year-olds had approximately 400 asymptomatic thoracic aneurysms per 100,000 autopsies, whereas 80-year-olds had a prevalence of 670 per 100,000 autopsies.¹⁶ The mean age at diagnosis is between 60 and 70 years. Men are diagnosed 10 years earlier on average and have a 2:1 to 3:1 predominance compared to women.¹⁵ In a study of residents in Olmstead county, the prevalence of thoracic aneurysms was 5.9 cases per 100,000 people-years prior to 1980.¹⁸ This number increased to 10.4 cases per 100,000 people-years between 1980 and 1994.¹⁹

Etiology and Risk Factors

Although there has been a long-standing belief that aortic aneurysms represent a late degenerative stage of atherosclerosis, this concept has been seriously challenged, and aneurysms are now viewed in terms of genetic and molecular mechanisms.¹⁵ Atherosclerotic disease is now thought to be associated with, rather than causative of, aneurysmal disease. Aneurysms associated with atherosclerosis of the aorta most commonly involve the descending or thoracoabdominal segments, whereas atherosclerosis is rarely associated with ascending aortic aneurysms.

1 Abnormal proteolysis, the presence of elastolytic serum enzymes and deficiencies of collagen and elastin have been implicated as factors contributing to the development of these aneurysms.¹⁷ Atherosclerotic lesions of the thoracic aorta may ulcerate and penetrate the internal elastic lamina of the aortic wall, which can result in hemorrhage within the layers of the media leading to intramural hematoma, an entity on the continuum of aortic dissection. Once aneurysmal dilatation of the aorta has begun, it tends to progress. Whether this is due to a gradual but constant increase in size or episodic incremental increases is unknown. Associated chronic obstructive pulmonary disease (COPD), smoking, and hypertension are known to be risk factors and can increase the rate of aneurysm growth. Other disorders with genetic predisposition are also highly linked with thoracic aneurysms and include Marfan syndrome, Loeys–Dietz syndrome, Ehlers–Danlos syndrome, and Turner syndrome (Table 85-1).

Degenerative

The most common etiology for TAA formation is cystic medial degeneration. Although the underlying mechanisms for this process are unknown, pathologic features include elastic fiber fragmentation, smooth muscle cell apoptosis, and local production of matrix-degrading enzymes, specifically matrix metalloproteinases (MMPs). The degree of atherosclerosis present in the aorta is dependent on the anatomy of the aneurysm. Ascending aortic aneurysms are degenerative often without extensive atherosclerosis, although atherosclerosis is often a feature associated with degenerative descending aneurysms. The pathogenesis of aortic aneurysms appears to be linked to a reduction in functional extracellular matrix proteins, elastin and collagen, either through enzymatic degradation or deficiencies in these structural proteins. Moreover, in some diseases with genetic predisposition, there is a shift to increased expression of MMPs as well as a reduction in tissue inhibitors of MMPs (TIMPs) resulting in degradation of the extracellular matrix. For example, patients with bicuspid aortic valves are known to have altered expression of MMPs and TIMPs.²⁰ As such, these patients have degenerative ascending aortic aneurysms often independent of any associated functional valve disease or atherosclerosis.

Figure 85-3. Reconstruction of a CT scan of an aortic root aneurysm in a patient with Marfan syndrome. Commonly the sinuses of Valsalva are involved with sparing of the aortic valve.

Genetically Triggered

Although the risk of TAA disease increases with age, thoracic aneurysms in young patients are most likely due to genetic predisposition or familial syndromes. Recently, several genetic etiologies linked to thoracic aneurysms have been elucidated. In particular, insights have been gained from a registry for the genetically triggered TAAs and cardiovascular conditions (GenTAC) which has genetic information on more than 1,000 patients with thoracic aneurysms secondary to hereditary or genetic predisposition.¹⁶ The most common and notorious disease is Marfan syndrome, which is an autosomal dominant defect of the fibrillin gene located on chromosome 15. Mutation of fibrillin leads to instability of the elastic fibers in the aortic media. The prevalence of aortic dilatation in Marfan syndrome is 70% to 80% and most commonly involves the aortic root and sinuses of Valsalva, rendering the aorta prone to rupture or dissection (Fig. 85-3). Marfan syndrome presents at an early age and tends to be more common in men than women. The cardinal features of the disorder include tall stature, ectopia lentis, mitral valve prolapse, aortic root dilatation, and aortic dissection. About three quarters of patients have an affected parent, while new mutations account for the remainder of cases.

Recently, mutations of transforming growth factor receptors I and II (TGFBRI, TGFBRII) termed Loeys–Dietz syndrome have been linked with thoracic aneurysms. These patients have a classic bifid uvula. Ehlers–Danlos syndrome encompasses a group of more than 10 disorders characterized by defects of collagen synthesis. The disease can range from hypermobility of the joints to extremely fragile skin and extreme muscle weakness. The common vascular Ehlers–Danlos (type 4) is caused by an autosomal dominant disorder of type III collagen. These patients are characterized by fragility of their blood

vessels. Familial thoracic aortic aneurysms and dissections (FTAAD) is caused by mutations of the α actin II or myosin heavy chain (MYH11).²¹ Turner syndrome is defined by the loss of an X chromosome (XO). Patients with Turner are prone to aneurysmal degeneration of their ascending aorta (Table 85-2).

Infectious and Inflammatory

In current practice, primary infections of the aorta are rare but do lead to aneurysms. Mycotic aneurysms can be caused by bacterial, fungal, spirochetal, or viral agents. Prior to the antibiotic era, syphilis accounted for approximately 75% of all aneurysms. Mycotic aneurysms occur due to localized infections in the aortic or arterial walls, usually as the result of bacteremia. Infection of atherosclerotic plaques themselves can also result in mycotic aneurysms. As a result of trauma or due to infected lymph nodes, infection may also spread to blood vessel walls contiguously. Pre-existing aortic aneurysms may also become infected, usually from bloodstream seeding. Although any pathogen may infect aneurysms, *Salmonella* species show a special proclivity for vascular tissues. Other organisms associated with mycotic aneurysms are *Staphylococcus* species, *Streptococcus* species, *Pasteurella multocida*, *Legionella anisa*, and *Escherichia coli*. Treatment consists of long-term antibiotics prior to and after surgical aneurysm resection.

Table 85-2 Known Genetic Mutations Associated with Aortic Aneurysms

Classification	Chromosome	Gene	Protein	Location	Frequency	Inheritance
Marfan	15q21.1	FBN1	Fibrillin 1	ECM	1:5,000–10,000	Dominant
Loeys–Dietz	3p24–25	TGFBR2	TGF β -R2	Cell surface	Rare	Dominant
	9q33–34	TGFBR1	TGF β -R1			
Ehlers–Danlos	2q24.3–31	COL3A1	Type III collagen	ECM	1:10,000–25,000	Dominant
ATS	20q13.1	SLC2A10	GLUT10	Intracellular	Rare	Recessive
AOS	15q22.2–24.3	Smad3	SMAD3	Intracellular	Rare	Dominant
TGFB2	1q41	TGFB2	TGF β 2	Intracellular	Rare	Dominant
Nonsyndromic						
TAAD2	3p24–25	TGFBR2	TGF β -R2	Cell surface	~3% of TAA	Dominant
TAAD4	10q23–24	ACTA2	Actin	Intracellular	10–15% of TAA	Dominant
TAAD5	9q33–34	TGFBR1	TGF β -R1	Cell surface	~2% of TAA	Dominant
TAAD-PDA	16p12–13	MYH11	β -MHC	Intracellular	1–2% of TAA	Dominant
	3q21.1	MYLK	MLCK	Intracellular	~1% of TAA	

ATS, arterial tortuosity syndrome; AOS, aneurysms-osteoarthritis syndrome; TAA, thoracic aortic aneurysm. Adapted from Elefteriades JA, Pomianowski P. Practical genetics of thoracic aortic aneurysm. *Prog Cardiovasc Dis* 2013;56(1):57–67.

A host of rare inflammatory diseases of the aorta and great vessels including Takayasu arteritis, Behçet disease, Kawasaki disease, and giant cell arteritis can result in TAAs and can require surgical treatment. Giant cell arteritis is a systemic arteritis that occurs in elderly patients, that commonly affects the temporal artery which can be biopsied for diagnosis.

Traumatic Pseudoaneurysm

Pseudoaneurysms are associated with previous operations or trauma to the aorta. Iatrogenic pseudoaneurysms occur following aortic surgery and can form at anastomotic or cannulation sites or areas where an aortic cross-clamp was placed. Infection should be strongly considered when encountering postsurgical pseudoaneurysms. Classically, rapid decelerating blunt trauma leads to aortic transection. In more than 50% of cases, the location of the aortic injury is just distal to the fixed ligamentum arteriosum, the remnant of the ductus arteriosus.^{22,23} For the 20% of patients who survive this acute event, the rupture is partially contained by the aortic adventitia and pleura. Aneurysmal formation around the site of injury can occur and often dilates faster because it is an unsuspected injury, and utmost care with regard to their antihypertensive therapy has to be taken to avoid rupture. Given multisystem injuries often present in these high-speed injuries, many consider endovascular aortic repair the preferred approach for most of these patients.²⁴

Diagnosis

Most TAAs are asymptomatic and are found incidentally. Symptomatic aneurysms are often diagnosed based on their anatomic sequelae. Patients with aneurysms of the ascending aorta may also present with fullness in the chest or signs and symptoms of aortic valve insufficiency. Acute chest pain may be caused

by either expansion of the aneurysm or dissection of the aortic wall. Arch and descending thoracic aneurysms can present with hoarseness secondary to stretching of the left recurrent laryngeal nerve, stridor from tracheal compression, or dysphagia from esophageal compression.

There are multiple imaging modalities to diagnose TAAs and dissections. Plain chest radiograph can be suggestive whereas computed tomography (CT), magnetic resonance imaging (MRI), and transesophageal echocardiography (TEE) are definitive studies.²⁵ CT is widely available and provides detailed information about the size, location, and extent of aortic disease as well as anatomic detail of surrounding mediastinal and thoracic structures. In particular, CT angiography with arterial phase contrast of the chest, abdomen, and pelvis is essential for operative planning. Critical elements to be gained from the CT include the following:

1. Aneurysm size, location, and extent
2. Presence of acute or chronic aortic dissection or intramural hematoma
3. Involvement and perfusion of branch vessels For endovascular considerations, the following elements are also essential to determine:
4. Angulation of Aortic Arch and Descending Aorta
5. Size of femoral and iliac vessels
6. Proximal and distal landing zones (a minimum of 2 cm of “normal” aorta is required)
7. Tortuosity of aorta and iliac vessels
8. Involvement of great vessels and/or visceral vessels

MRI/MRA offers detailed anatomy as CT does, but does not require radiation. Moreover, MRI may be particularly useful in pregnant patients. However, MRI requires lengthy image acquisition and processing times, is not as readily available as CT, and cannot be performed in patients with significant metallic implants, such as pacemakers and defibrillators. In addition, gadolinium contrast used in MRA is also nephrotoxic.

TEE avoids the use of these agents and offers good visualization of the ascending and descending thoracic aorta as well as cardiac structures. Due to tracheal shadowing, TEE does not provide reliable visualization of the aortic arch. After CT scanning, TEE is the second most common study used to diagnose aortic dissection with 90% to 99% sensitivity. In unstable patients with a high degree of clinical suspicion for aortic dissection, a confirmatory TEE in the operating room may be safer and more expedient than CT scanning. Although widely available, TEE does require specialized training and operators.

Management and Natural History

Currently, the only assessment tool to determine the risk of catastrophic aortic dissection or rupture is related to aneurysm size and rate of growth. It is likely that other biologic factors may help stratify risk, but as yet, these have yet to be proven. Data from the Yale Center for Thoracic Aortic Disease, which have followed more than 3,000 patients with TAAs, have suggested that the risk of aortic complications in the ascending aorta increases significantly as the size approaches 6.0 cm, and in the descending thoracic aorta as the size approaches 7.0 cm.²⁶ Similarly, the Olmstead County registry (Minnesota) reported that a rupture rate of 16% at 3 years for 6-cm aneurysms compared to 31% for 7-cm aneurysms.¹⁹ The Yale group has reported the annual risk of death or aortic-related complication exceeds 15% in patients with aneurysms of 6.0 cm or greater compared to 5% in patients with aneurysms smaller than 5.0 cm. Other studies have supported this pattern, reporting a mean rate of rupture or dissection of 2% per year for small aneurysms, 3% for aneurysms 5.0 to 5.9 cm, and 6.9% for aneurysms 6.0 cm or greater in diameter.^{27,28} These data have formed the basis for size criteria to intervene prior to the attainment of the previously mentioned dimensions in an asymptomatic patient. Similar to other aneurysms, the growth of TAAs is indolent. The typical rate of growth for ascending aortic aneurysms is 0.1 cm/yr and for descending aneurysms is 0.3 cm/yr.²⁶

Medical Management

Medical management of aortic aneurysms targets mechanisms to reduce aortic wall stress.²⁹ Lifestyle changes to avoid high-intensity exercise, such as weight lifting or sprinting, should be encouraged. Anti-impulse therapy is the primary pharmacologic therapy for aortic aneurysms, with a goal of reducing overall blood pressure and the rate of change in aortic pressure over time (dP/dT). While β -blockers and angiotensin-converting enzyme inhibitors/angiotensin receptor blockers are common treatments, their efficacy is unproven and studies are currently underway in patients with aortic aneurysms.

Smoking cessation may be helpful in patients who have not developed COPD. The diagnosis of COPD is a significant risk factor for aortic complications. It is unclear if risk factor modification of COPD once diagnosed can influence the likelihood of aortic rupture. Frequent imaging of these patients to assess changes in size should be performed to determine if surgery should be recommended. Present surveillance recommendations from the American Heart Association are repeat imaging at 1, 3, 6, and 12 months and, if stable, annually thereafter.²⁹

Surgical Indications

Since thoracic aneurysms increase in size until they rupture, the decision to intervene is critical. All symptomatic TAAs meet indications for surgical intervention. Preemptive surgical therapy should be applied at a size of 5.5 cm for ascending and arch aneurysms and 6.0 to 6.5 cm for descending aortic aneurysms in suitable surgical candidates to avoid aortic complications or death (Table 85-3).^{28,30} These surgical threshold criteria should be modified for patients with Marfan syndrome or connective tissue disease in which preemptive surgery is appropriate at 4.5 cm for root and ascending aneurysms and 5.5 cm for descending aneurysms.³¹ Some have further suggested that patients with Turner syndrome be treated surgically if the aortic diameter exceeds 4.0 cm due to the aggressive nature of aortic disease in these patients. Similarly, for patients with bicuspid aortic valves a size threshold of 5.0 cm is recommended for ascending aneurysm intervention.³² Furthermore, any patient with symptoms or rapid growth as seen on sequential CT scans should have surgical intervention in a timely manner. Growth rates exceeding 5 to 7 mm/yr for aneurysms or greater than 5 mm per 6 months for chronic aortic dissections are considered harbingers of aortic complications, and earlier intervention should be considered.

Table 85-3 Typical Size Indications for Aortic Surgery

Ascending Aorta	Size Threshold (cm)
Normal	5.5
Bicuspid aortic valve	5.0
Concomitant cardiac surgery (CABG, AVR, etc.)	4.5
Marfan syndrome or other connective tissue disorders	4.5
Turner syndrome	4.0
Descending Thoracic Aorta	
Normal	6.0
Marfan syndrome or other connective tissue disorders	5.5

Typical size indications for aortic surgery based on absolute aortic diameter. Aortic Size Index, determined by ratio of aortic diameter to body surface area, also play an important role in determining surgical indications. Growth rates also determine timing of surgical intervention.

Open Surgical Management of TAA

2 Careful planning by experienced medical personnel is paramount to providing optimal treatment in patients with TAAs as the morbidity and mortality for surgical intervention are significant. Over the years there have been substantial improvements in the intraoperative and postoperative management in patients with TAA. The approach and techniques of repair vary widely based on the location of the thoracic aneurysm.

Once the need for intervention has been determined, a full cardiac evaluation should be completed including angiographic evaluation of coronary arteries and echocardiography. The basic premise of open surgical repair for aneurysms, regardless of the situation, is replacement with an interposition graft. Cardiopulmonary bypass, cerebral and visceral organ perfusion, and protection strategies are determined by the location and extent of aneurysm resection. Intraoperative management is essential with central venous pressure and arterial monitoring as well as large-volume intravenous infusion lines. Intraoperative TEE is useful to monitor fluid status and cardiac function during the operation.

Aortic Root and Ascending Aortic Aneurysms

3 Open surgical repair remains the mainstay for aortic root, ascending aortic, and aortic arch aneurysms with very acceptable outcomes and low morbidity when performed in centers of excellence. Operations to replace aortic root and ascending aorta are approached via a median sternotomy. All pathologic

segments of the aorta are evaluated and replaced if abnormal, including the aortic valve, sinuses of Valsalva, the tubular portion of the ascending aorta, and the aortic arch. Cardiopulmonary bypass is established through right atrial (venous) cannulation and either aortic, femoral, or axillary arterial cannulation. The left ventricle is vented via the right superior pulmonary vein. The use of the axillary artery for cannulation allows for selective antegrade cerebral perfusion if circulatory arrest is needed during the replacement of the aorta (Fig. 85-4).^{33,34} The axillary artery is exposed via a 4-cm transverse incision 2 cm below and parallel to the clavicle. Once through the pectoral muscles, the axillary vein is isolated and retracted, exposing the axillary artery. After systemic heparinization, an 8- or 10-mm Dacron graft is anastomosed in an end-to-side fashion onto the artery. The arterial cannula is then secured to the Dacron graft. Myocardial protection is achieved by infusion of antegrade blood cardioplegia into the coronary ostia and retrograde cardioplegia into the coronary sinus accompanied by a topical hypothermia.

If the aneurysm is contained to the root or ascending aorta and does not involve the aortic arch or head vessels, the heart can be arrested with the cross-clamp proximal to the innominate artery, and mild hypothermia can be used for systemic protection while the patient is maintained on cardiopulmonary bypass. A tube graft is then anastomosed distally and proximally using running monofilament suture. The aortic valve is also assessed with the aorta open and the valve repaired or replaced as necessary (Fig. 85-5). If the dilation of the aorta extends into the arch, deep HCA allows for complete resection and reconstruction of the diseased aorta and an open distal anastomosis in a bloodless field. Cerebral protection can be augmented by maintaining antegrade cerebral perfusion via the right axillary cannula and clamping the proximal innominate artery. The distal anastomosis is then performed in a timely manner. The cross-clamp is then reapplied to the graft, and full cardiopulmonary bypass can then resume. The proximal anastomosis is then completed encompassing all diseased portions of the ascending aorta and the aortic root.

Figure 85-4. Cannulation of the right axillary artery with the use of a side graft. Once established, axillary artery cannulation can allow for antegrade cerebral perfusion throughout the aortic replacement procedure.

Figure 85-5. Common repair options include: (A) graft replacement of the ascending aorta from the sinutubular junction to the aortic arch, (B) graft replacement with concomitant aortic valve replacement, (C) total aortic root replacement and ascending aortic replacement with a valve conduit and coronary reimplantation (Bentall procedure), and (D) Valve-sparing aortic root reimplantation where the native aortic valve is left in-situ (David procedure).

Aneurysms involving the aortic root require isolation of the right and left coronary ostia and reimplantation into the Dacron tube graft. Care must be taken to ensure the coronary arteries are not kinked. In this setting the native aortic valve can be spared (valve-sparing root replacement) if the leaflets are normal or can be replaced with a valved conduit (Bentall procedure).

Aortic Arch Aneurysms

Operations involving replacement of the thoracic aortic arch are approached from a median sternotomy and use HCA. In this setting, the patient is cooled to 16°C to 24°C and the cardiopulmonary bypass circuit is turned off for up to 45 to 60 minutes. The use of selective antegrade cerebral perfusion (cannulation and perfusion of the right axillary artery with a clamp on the proximal innominate artery) allows perfusion of the right carotid and vertebral arteries during operations of the aortic arch, and reduces the risk of embolism and associated morbidity by maintaining some perfusion to the brain.³⁵ With selective antegrade cerebral perfusion, the patient may require less systemic hypothermia allowing for reduced bypass times. Replacement of the arch is often best performed with the use of a multibranched aortic graft to allow individual anastomoses to each of the three great vessels (Fig. 85-6).^{35,36} This approach, rather than reimplanting an island of aortic tissue with all the great vessels, has been suggested to reduce the risk of embolization but, more importantly, minimizes the risk of late aneurysmal degeneration of the aortic patch.³⁶

Descending Thoracic Aortic Aneurysms

Open surgical repair of the descending thoracic aorta is performed through a left posterolateral thoracotomy. The exact interspace depends on the proximal and distal extent of the disease. Prior to positioning, a double-lumen endotracheal tube is placed for single-lung ventilation. A variety of adjuncts have been devised to ameliorate the most common complications of stroke, paralysis, and visceral organ malperfusion during descending thoracic aneurysm repair.³⁶ Cerebrospinal fluid (CSF) drainage with a lumbar drain allows intra- and postoperative monitoring of CSF pressure and drainage and has been shown to reduce the incidence of paraparesis and paraplegia caused by spinal cord ischemia.³⁷ Other modalities used to mitigate risk of spinal cord injury include monitoring of sensory evoked potentials and motor evoked potentials.^{38,39} Pharmacologic agents, including barbiturates, naloxone, and steroids,

may also help reduce neurologic injury when administered during the procedure. In addition, epidural catheters are extremely beneficial for pain control and can improve early mobilization and pulmonary function.

Figure 85-6. Traditional total arch repairs. **A:** Island approach. **B:** Branched graft approach. **C:** Traditional elephant trunk (shown with concomitant island approach).

Figure 85-7. Schematic of left heart bypass whereby partial bypass is used to maintain perfusion to the viscera and lower extremities. The inflow to the Bio-Medicus pump is the left inferior pulmonary vein, and the outflow is the left femoral artery. This technique avoids the need for an oxygenator.

There are two options to perform this procedure: sequential clamping versus HCA. The use of left heart or partial cardiopulmonary bypass has been shown to decrease the risk of visceral and spinal cord ischemia. If the arch is relatively spared and enough normal aorta can be identified distal to the left common carotid artery, a proximal clamp can be placed, which allows for left heart bypass. In using left heart bypass, the left atrium via the left inferior pulmonary vein and the femoral artery are cannulated. A centrifugal pump, heparin-bonded tubing, and minimal heparinization can be used, which can result in less bleeding than in traditional cardiopulmonary bypass. With this technique, mild hypothermia is used

with sequential aortic clamping, reimplantation of critical intercostal arteries, and the distal anastomosis constructed with peripheral and visceral perfusion via the femoral artery (Fig. 85-7).⁴⁰ Conversely, for patients in whom the transverse arch cannot be safely clamped, profound HCA is used for both cardiac protection and central and peripheral nervous system protection. With this technique, full cardiopulmonary bypass with cannulation of the femoral artery and femoral vein allows for cooling of the patient and deep HCA and the proximal anastomoses can be performed in a bloodless field.⁴¹

After clamping the aorta (or initiating HCA), the aneurysm is opened and the proximal cuff is fashioned. An interposition graft is sutured to the proximal aorta in an end-to-end fashion. Once completed, cardiopulmonary bypass can be reinstituted and the graft clamped to perform the distal anastomoses when using HCA. The distal aorta and graft are then fashioned and an anastomosis created. Significant lumbar artery identified via preoperative computed tomographic aortography or intraoperative assessment can be reimplanted into the interposition graft. There is continued controversy regarding the necessity to perform this as this process can often take more than 30 minutes during which the aorta may be clamped. Once the affected portion of aorta has been successfully replaced, the patient can be appropriately warmed and hemostasis ensured. The patient is removed from cardiac support and thoracotomy closed in the usual manner. If the diaphragm was taken down, it should be reapproximated with interrupted nonabsorbable suture.

Endovascular Therapy

4 Thoracic endovascular aneurysm repair (TEVAR) for the descending thoracic aorta has become the preferred treatment approach not only for aneurysms but also for dissections and traumatic aortic injuries as they often can be performed with less morbidity than that associated with open surgical treatment. Endovascular stent grafts are available in a wide range of sizes and are made of polytetrafluoroethylene (PTFE) or woven polyester with steel or nitinol stents to maintain their shape. Absolute contraindications for TEVAR include insufficient proximal and distal landing zones, or excessive aortic tortuosity. Relative and debated contraindications include connective tissue disease (such as Marfan's), young age, or patients unlikely to follow-up. Patients who are not candidates for endovascular repair require open repair.

Planning for TEVAR requires careful review of all imaging. Proximal and distal landing zones with a minimum of 2-cm "normal" aorta are preferred. To prevent endoleaks, stent grafts are oversized by approximately 10% to 15% from the CT cross-sectional diameter. The size of the femoral and iliac arteries must be large enough to allow safe passage of the delivery sheaths. In general, vessels should be 7 to 8 mm depending on the size of the chosen stent graft. In some cases, an adequate proximal landing zone can only be accomplished by coverage of the left subclavian artery. If the left subclavian is covered, a carotid to subclavian bypass can be considered to prevent spinal cord ischemia, subclavian steal, and limb ischemia. In cases where the patient has a patent left internal mammary bypass graft or an incomplete circle of Willis with a left vertebral artery that terminates in a posterior inferior cerebellar artery, a carotid subclavian bypass should be performed prior to TEVAR.

TEVAR is performed by first obtaining femoral or iliac access. For smaller grafts this can be done with all percutaneous access and use of closure devices. In other cases, a femoral or iliac cutdown is performed. A stiff wire is advanced into the aortic root under fluoroscopic guidance. A separate pigtail catheter is advanced over a wire into the aortic root for aortography. The stent graft is then advanced into the appropriate position over the stiff wire. Once in place, an aortogram is performed to ensure proper positioning. A completion angiogram is performed to ensure no positioning, presence of kinks or endoleaks, or continued filling of the aneurysm sac. A type 1A (proximal) or type 1B (distal) endoleak typically requires placement of an additional stent graft (Fig. 85-8).

Hybrid Procedures

As endovascular approaches have evolved, so too have the options for hybrid procedures combining open and endovascular surgery. Patients with combined arch and descending thoracic aneurysms are often ideal candidates for hybrid procedures. The traditional approach has been a two-stage open procedure (elephant trunk). In the first operation, the arch aneurysm is repaired under HCA via a median sternotomy. The distal end of the Dacron graft replacing the arch is sewn to the proximal descending aorta with a long cuff to allow for future repair of the descending aortic aneurysm in the second stage. In the second stage, the traditional procedure has been an open descending aneurysm repair using the long cuff left at the initial operation as the proximal new aorta. Stent graft therapy has allowed for the second stage to be performed less invasively with an endovascular approach. An alternative approach to these patients is debranching of the arch vessels via sternotomy using a

trifurcated graft off the ascending aorta to the great vessels. This can be performed without the use of cardiopulmonary bypass using a side-biting clamp on the ascending aorta. This is followed by endovascular repair of the arch and descending aorta covering the native take off of the great vessels. Other patients who benefit from hybrid procedures include those with thoracoabdominal aneurysms who require debranching of visceral vessels prior to stent graft repair. The inflow for these debranching bypasses is traditionally from the iliac vessels but can include the proximal abdominal or descending thoracic aorta.

Figure 85-8. Reconstruction of a CT scan in a patient with a descending thoracic aneurysm (A) prior to repair, and (B) after endovascular stent graft repair showing successful exclusion of the aneurysm sac.

Outcomes and Complications

With advances in surgical techniques significant improvements in morbidity and mortality with aortic aneurysm surgery have been made. Important outcomes following aortic surgery include mortality, stroke, paralysis, renal failure, and freedom from reoperation. Operative mortality for elective ascending aortic aneurysm repair is low, ranging from 1.2% to 3.7% in contemporary series.^{42–45} Risk factors for mortality include advanced age, coronary artery disease, heart failure, reoperative sternotomy, and need for HCA. Interestingly, patients with connective tissue disorders, such as Marfan syndrome, have a low operative mortality of 1.5%, partially due to their young age at time of presentation.⁴⁶ The primary morbidity following ascending aortic surgery is bleeding and stroke. Reexploration for bleeding occurs in 5.6% to 9.9% of patients.⁴⁵ Precise suturing with even tension and minimal aortic tissue trauma is essential to minimize bleeding risks. Use of Teflon felt material and hemostatic agents may further reduce bleeding. Neurologic injury following surgery occurs in 3.2% to 9.8% of patients.⁴⁵ Stroke is usually due to embolization of debris or thrombus from the aorta resulting in focal deficits. Diffuse injury is attributed to microemboli, insufficient cooling, and prolonged circulatory arrest. The use of cerebral perfusion appears to improve these outcomes.⁴⁷ The need for late reoperation occurs because of pseudoaneurysm formation, graft infection, or progressive aortic enlargement. Reoperation carries significantly greater operative mortality ranging from 4% to 22%.⁴⁸ Up to 60% of reoperations occur because of inadequate repair during the primary operation and can be avoided if all aneurysmal tissue is resected.⁴⁹ Some patients, particularly those with connective tissue disorders, have progressive aortic pathology and are prone to reoperation. Pseudoaneurysm formation may be the result of a technical error, infection, or inadequate resection of diseased segments. Graft infections are reported in 1.0% to 6.0% of patients, are associated with very high operative mortality and often require a homograft for repair.⁵⁰

More extensive aortic operations involving the aortic arch are associated with greater risks of mortality and morbidity. Operative mortality has ranged from 5% to 8% in contemporary series with stroke risks of 5% to 12%.^{51,52} As arch surgery requires longer circulatory arrest times, increased incidences of renal failure of 3% to 7% are noted.

Similar to ascending aneurysm surgery, mortality with open repair of descending thoracic aneurysms has significantly improved. Contemporary open elective repair is associated with an operative mortality of 5%.⁵³ The major complications include stroke (2% to 10%), paralysis (5% to 10%), renal failure

(13%), and recurrent laryngeal nerve injury (40%). Increased extent of aortic replacement correlates with risks of paralysis. The use of adjuncts such as CSF drainage, intercostal artery reimplantation, and distal aorta perfusion with cardiopulmonary bypass or left heart bypass has significantly reduced incidence of paraplegia and renal failure.^{54,55}

Endovascular therapy has emerged as the first-line therapy for descending TAAs. In most series, perioperative mortality ranges from 1.9% to 3.1% for elective TEVAR.⁵⁶ Complications include stroke (4% to 8%), paralysis (3% to 11%), and access site complications. The risk of stroke with TEVAR increases with more proximal deployment in the arch, the presence of mobile atheroma in the arch, and history of cerebrovascular disease. Longer segment aortic coverage increases risk of paralysis. Use of adjuvants such as CSF drainage or carotid-subclavian bypass when the left subclavian is covered reduces incidence of paraplegia. Multiple studies have supported these findings reporting lower mortality, paraplegia, and renal failure following endovascular therapy versus open surgery for the descending thoracic aorta.^{24,57}

Long-term data on TEVAR are limited due to its recent and evolving development. In a 5-year follow-up of the Gore TAG Food and Drug Administration trial, aneurysm-related mortality was 2.8% compared to 11.7% for nonrandomized open surgical controls.⁵⁷ The rate of endoleak was 4.3%, which in other studies, ranged from 4% to 8%. The most common endoleak is a type 1A (proximal). Graft migration can occur in 1% to 2% of patients. The rate of reintervention is estimated to be 10.8% at a median 5.6 months, primarily for type 1 and type 3 endoleaks.

THORACIC AORTIC DISSECTION

History

In 1760, King George II of England died at Kensington palace while “straining on the toilet.” His personal physician, Dr. Frank Nicholls performed an autopsy and provided the first description of a thoracic aortic dissection. He stated “in the trunk of the aorta we found a transverse fissure on its inner side, about an inch and half long, through which some blood had recently passed under its external coat and formed an elevated ecchymosis.”⁵⁸ King George died from acute aortic dissection with rupture and cardiac tamponade. The first successful surgical approaches to acute aortic dissection were described by DeBakey and associates in 1954.⁵⁹

Prevalence and Classification

Acute aortic dissection is the most frequent lethal condition of the aorta. Aortic dissections are classified based on anatomic involvement and extent. Two classification systems are widely utilized: the DeBakey and the Stanford systems. In the DeBakey system, a type 1 dissection extends from the ascending aorta into the descending thoracic aorta, possibly to the aortic bifurcation (Fig. 85-9). Type 2 dissection involves the ascending aorta and terminates proximal to the left subclavian artery. Type 3 dissection starts distal to the left subclavian artery and involves the descending or abdominal aorta. The Stanford classification has become more commonly used as it readily translates to clinical decision making.⁶⁰ A Stanford type A dissection involves the ascending aorta and includes DeBakey type 1 and type 2. A Stanford type B dissection involves the descending aorta only, similar to DeBakey type 3. Type B dissections are now further subclassified as complicated versus uncomplicated. Complicated type B dissections are defined by uncontrolled pain, impending rupture, or visceral organ malperfusion. Acute aortic dissection is three times more frequent than thoracic or abdominal aortic rupture.¹⁵ The estimated worldwide prevalence is 2.95 per 100,000 per year, with an estimated 2,000 new cases in the United States each year.⁶¹ Stanford type A dissection constitutes 75% of acute aortic dissections.

Etiology and Risk Factors

Aortic dissection is initiated when a weakened aortic wall is exposed to a high impulse force. The most common primary tear occurs in the right anterior aspect of the ascending aorta, likely due to the impulse force of blood ejected from the left ventricle. Once this entry tear occurs, blood enters the aortic media and propagates, creating a false channel of flow. The false channel may propagate antegrade, retrograde, or both. When the false channel encounters a branch vessel, the origin of the branch vessel may tear off, leading to a fenestration with communication between the true and false lumens. The branch vessel will then derive some or all of its blood flow from the false lumen. The patency and origin of branch vessel perfusion is critical in determining treatment plans for patients with

acute aortic dissection. Although the false lumen may end blindly 4% to 12% of patients leading to false-lumen thrombosis, the vast majority of patients have multiple fenestrations leading to false-lumen patency. In chronic dissection, the false-lumen remodels over time, leading to further aneurysm formation and possibly rupture.

Figure 85-9. Debakey classification system for aortic dissection. Stanford type A = Debakey type 1 or type 2. Stanford type B = Debakey type 3A or 3B.

Diagnosis

Acute aortic dissection has been described as the “great imitator,” as symptoms are often ascribed to other pathologies, such as myocardial infarction, peptic ulcer disease, or musculoskeletal back pain. For this reason, diagnosis of aortic dissection can be delayed. Dissections usually present with pain involving the chest, back, or abdomen. The location of maximum pain tends to change as the dissection progresses. Involvement of branch vessels may lead to syncope, stroke, paralysis, myocardial ischemia, mesenteric ischemia, or limb ischemia. Aortic root involvement may lead to acute aortic insufficiency and symptoms of acute heart failure. Pericardial effusions can present with cardiac tamponade symptoms.

Management and Natural History

5 Once aortic dissection occurs, mortality and morbidity are high. Fifty percent of patients with acute Stanford type A dissection die within 48 hours if untreated. Data suggest a 1% per hour rate of mortality from the onset of symptoms. The most frequent causes of death are aortic rupture, tamponade, heart failure, and cerebral or visceral organ malperfusion. In contrast, acute mortality of type B aortic dissection is lower with 90% in-hospital survival.⁶² Survivors of aortic dissection then develop a chronic aortic dissection characterized by aortic remodeling and progressive aneurysm enlargement. The annual growth rates for patients suffering from chronic dissections are significantly higher than nondissected aneurysms, ranging from 0.24 to 0.48 cm/yr.

Acute Stanford type A aortic dissections mandate emergent surgery. Complicated type B aortic dissections, characterized by uncontrolled pain, impending rupture, or visceral organ malperfusion, also require intervention with open or endovascular techniques. Intervention for chronic dissection is

indicated for aneurysm enlargement with size criteria similar to nondissected aneurysmal disease.

Surgery for Type A Aortic Dissections

Operative intervention for acute type A aortic dissection is focused on the aortic root, ascending aorta, and aortic arch to eliminate the common causes of death of aortic rupture, cardiac tamponade, myocardial ischemia, stroke, and heart failure. A successful operation for type A dissections reconstructs the root with a well-functioning valve, replaces the ascending aorta and the proximal arch maintaining true-lumen patency of the arch vessels. Depending on the extent of the dissection, arterial cannulation can be challenging. The most common sites of cannulation include the right axillary and femoral arteries, however, alternative strategies such as cannulating the true lumen of the dissected ascending aorta using an ultrasound guided Seldinger technique may also be performed.⁶³ Once the patient is cooled on cardiopulmonary bypass to an adequate temperature for HCA, the ascending aorta is resected. Often this performed with selective antegrade cerebral perfusion via the right axillary artery or with retrograde cerebral perfusion by a separate cannula placed in the superior vena cava. The ascending aorta is then replaced with an interposition graft from the sinotubular junction to the aortic arch. In rare situations, the aortic arch is so disrupted, a total arch reconstruction is performed. If the aortic root is dissected, the root is reconstructed and the aortic valve resuspended (Fig. 85-10). If there is significant pre-existing aortic root disease a root replacement or valve-sparing root procedure may be performed.

Figure 85-10. Dissected aortic root. The right and left coronary arteries (A) are rarely avulsed but if so require bypass. The aortic valve is resuspended using pledgeted mattress sutures (B) at the aortic valve commissures to allow valve coaptation. Felt and/or biogluue (C) is utilized to fill the dissected space as “neo media.”

Endovascular Therapy

Endovascular therapy has a growing and vital role in the acute and chronic management of type A and type B aortic dissections. For acute type A aortic dissections, endovascular therapy may be urgently performed to alleviate abdominal malperfusion. In patients who present with mesenteric ischemia, endovascular fenestration, celiac or superior mesenteric artery stenting may be utilized to improve visceral perfusion prior to proximal aortic surgery.

TEVAR has an increasing and evolving role in patients with acute and chronic type B aortic dissections and residual dissections following type A dissection repair. Preoperative CT angiography must be carefully reviewed to understand the anatomy and extent of the proximal fenestrations, the true and false lumen, as well as proximal and distal landing zones (Fig. 85-11). True-lumen arterial access may be gained percutaneously or with a femoral cutdown. Intravascular ultrasound (IVUS) is typically utilized to confirm true-lumen position. For dissections, grafts are not oversized to minimize the chance of rupture or retrograde dissection. The extent of coverage depends on the pathology being treated, but typically involves coverage of the entire descending thoracic aorta. Completion aortography is essential to identify any endoleaks and ascertain visceral perfusion following device deployment.

Outcomes and Complications

Outcomes following surgery for type A aortic dissection have improved, however significant morbidity and mortality remain. The International Registry of Acute Aortic Dissections (IRAD) reported the outcomes of 526 patients at 18 centers.⁶⁴ Overall hospital mortality was 25%. The most common causes of death included aortic rupture (33%), stroke (14%), abdominal malperfusion (12%). Risk factors for

increased mortality included age, extent of dissection, hemodynamic instability, and time since onset of symptoms. Long-term survival for patients who survive was 96% at 1 year and 91% at 3 years.

Figure 85-11. TEVAR for acute type B dissection.

Similar improvements have been made with open surgery for complicated type B dissections. In the most recent IRAD series, operative mortality was 29%, with a stroke rate of 9%, paraplegia rate of 5%, and renal failure rate of 8%.⁶² Results have improved with TEVAR. In a recent meta-analysis of 609 patients with type B aortic dissection, perioperative mortality was 5% with a 3% rate of stroke and 2% rate of retrograde aortic dissection.⁶⁵ In the IRAD data, TEVAR was associated with a lower mortality (11% vs. 34%) and complication rate (21% vs. 40%) compared to open surgery. Interestingly, mortality following TEVAR was similar to those patients managed medically who presumably had uncomplicated dissections. Importantly, the IRAD data were nonrandomized and subject to treatment bias which should limit overarching conclusions. Nevertheless, the data suggest that TEVAR is associated with significantly less morbidity and mortality than open surgical repair.

Based on this favorable data with complicated type B dissections, TEVAR is now being evaluated for uncomplicated type B dissections. Uncomplicated acute type B aortic dissections have a favorable in hospital survival of 89% to 93% with medical therapy alone.⁶⁶ The long-term outcomes however are not favorable with only 78% surviving at 3 years.⁶⁷ Two European randomized trials have been conducted to evaluate the outcomes of TEVAR for uncomplicated type B dissection. The INvestigation of STEnt grafts in Aortic Dissection (INSTEAD) trial has been recently published.⁶⁸ At 2 years, TEVAR failed to improve 2-year survival in comparison to medical therapy alone. Favorable aortic remodeling, such as true-lumen size and false-lumen thrombosis; however, occurred in 91% of TEVAR patients compared to 19% of medical only patients. The ADSORB (Acute Uncomplicated Aortic Dissection type B) trial also demonstrated favorable aortic remodeling after TEVAR.⁶⁹ In 61 randomized patients, TEVAR increased true-lumen size, decreased false-lumen size, and reduced overall aortic diameter. In longer-term data, this favorable aortic remodeling appeared to have led to improved survival. At 5 years, the INSTEAD trial data demonstrated improved aorta-specific mortality with TEVAR (6.9% vs. 19.3%) compared to medical therapy alone.⁷⁰ More long-term data are required to determine the utility of TEVAR for uncomplicated type B dissection.

CONCLUSIONS

Aneurysm disease of the thoracic aorta has a high morbidity and mortality, especially after the development of an aortic dissection. Treatment of these patients requires careful preoperative planning, meticulous protection of the viscera and spinal cord, and rigorous follow-up. Endovascular therapy has become the preferred technique for descending thoracic aortic disease and offers patients less morbidity than that associated with open surgical treatment. The best outcomes for all patients who suffer from aneurysm disease of the thoracic aorta are provided by a multidisciplinary approach with a firm understanding of the pathogenesis and natural history of the disease.

Chapter 86

Pericardium

Jules Lin

Key Points

- 1 Prompt recognition and treatment of cardiac tamponade can be lifesaving.
 - 2 The echocardiogram is the most useful noninvasive test in evaluating pericardial disease.
 - 3 The electrocardiogram is important in the diagnosis of acute pericarditis and classically shows diffuse ST elevations.
 - 4 The hemodynamic significance of a pericardial effusion depends on the volume and the rate of accumulation.
 - 5 Postoperative tamponade should always be in the differential diagnosis with low cardiac output after cardiac surgery.
 - 6 Distinguishing constrictive pericarditis from restrictive cardiomyopathy can be difficult but is important since the treatment is significantly different.
 - 7 Metastatic disease is the most common cause of pericardial effusion.
 - 8 Reconstruction of the pericardium should be considered to reduce adhesions in cases where a future redo sternotomy is likely and is important when there is a risk of cardiac herniation after an intrapericardial pneumonectomy.
-

1 The pericardium supports and protects the heart. The smooth pericardial surface and the small amount of normal pericardial fluid provide a frictionless chamber improving cardiac efficiency as well as serving as a barrier to infection. The pericardium can be susceptible to a variety of disease processes including inflammation, infection, malignancy, and trauma. Changes in compliance and the accumulation of pericardial fluid can impair cardiac function, and the prompt recognition and treatment of cardiac tamponade can be lifesaving.

HISTORY

Hippocrates first described the pericardium in 460 BC. Three hundred years later, Galen described a pericardial effusion and the inflammatory changes associated with pericarditis. Lower first reported pericardial tamponade in humans in 1669. Lancisi and Morgagni described constrictive pericarditis, and Laennec wrote of the “bread and butter” appearance of acute pericarditis in 1819.¹ Kussmaul described the hemodynamic changes known as pulsus paradoxus, and Beck and Griswald performed experimental studies in the 1930s leading to a better understanding of the pathophysiology of pericardial effusion.^{2,3} Karaeneff first described relieving the symptoms of tamponade using pericardiocentesis in 1840.⁴ Rehn reported methods to resect the pericardium in 1913.⁵

EMBRYOLOGY AND ANATOMY

The pleuropericardial membranes fuse during the fifth week of gestation dividing the thoracic cavity into pleural and pericardial spaces and forming the fibrous pericardium.⁶ The serous pericardium is a single layer of mesothelial cells that produce and reabsorb pericardial fluid. The serous and fibrous pericardium form the parietal pericardium which is normally 2 mm in thickness. The visceral pericardium covers the heart and the intrapericardial great vessels. The phrenic nerves are contained in the parietal pericardium, and there is a risk of diaphragmatic paralysis with any operation on the pericardium. The pericardial folds form the oblique sinus, a blind cul-de-sac behind the left atrium, and the transverse sinus between the aorta and pulmonary artery superiorly and the left and right atrium

inferiorly (Fig. 86-1). Lymphatic drainage is to the bronchial and tracheal lymph nodes and the thoracic duct. The pericardium normally produces 15 to 50 mL of serous fluid with a protein level lower than plasma.⁷

NORMAL PHYSIOLOGY

Although there are no significant consequences of the congenital absence or surgical resection of the pericardium as long as the defect does not lead to cardiac herniation, the pericardium has some function in the normal patient. The pericardium anchors the heart and prevents torsion and acute distension.⁸ The pericardium contributes to the diastolic coupling of the ventricles along the Starling curve. Mechanoreceptors in the pericardium may also regulate blood pressure and heart rate. The pericardium stretches up to 20% with small changes in pressure but becomes abruptly stiff and resistant with larger volumes. Compliance depends on the rate of fluid accumulation, and the hemodynamic response is also partially dependent on intravascular volume status.

The normal pericardial pressure is less than atmospheric pressure and is the same as the intrapleural pressure. With inspiration, right-sided venous returns and preload increases. Blood pools in the lungs and decreases left-sided venous return and aortic blood flow. The arterial pressure normally decreases less than 10 mm Hg with inspiration. The normal jugular waveforms are shown in Figure 86-2. The a wave is the normal atrial contraction. The c wave reflects the bulging of the atrioventricular valve into the atrium during isovolumic ventricular systole. The v wave represents passive atrial filling from the vena cava. The x descent occurs with systolic collapse during ventricular systole and atrial relaxation. The y descent reflects diastolic collapse with opening of the atrioventricular valve and passive ventricular filling. Inspiration decreases intrathoracic pressure and leads to a lower x descent compared to the y descent.

Figure 86-1. This drawing illustrates the pericardial attachments of the great vessels and pulmonary veins. The oblique sinus forms a blind cul-de-sac behind the left atrium, and the transverse sinus is a space between the aorta and pulmonary artery superiorly and the left and right atrium inferiorly.

DIAGNOSTIC STUDIES

While the electrocardiogram is nonspecific, it can be helpful in suggesting the diagnosis. In acute pericarditis the EKG classically shows diffuse ST elevations, and a low-voltage QRS is seen with a large pericardial effusion. The chest radiograph in a patient with a pericardial effusion shows an enlarged cardiac silhouette described as a water bottle. Pericardial calcification can be seen in chronic constrictive pericarditis secondary to tuberculosis.

2 The echocardiogram is the most useful noninvasive test in evaluating pericardial disease. The echocardiogram can identify an effusion, pericardial thickening, or masses. By using Doppler and assessing changes in chamber size, echocardiogram is useful in assessing hemodynamics and can help

differentiate tamponade, constriction, and restriction. It can also be used to help guide procedures like pericardiocentesis. Computed tomography and magnetic resonance imaging can identify pericardial masses and pericardial thickening or calcification.⁹ Cardiac catheterization provides pressure tracings that help to distinguish cardiac tamponade, constriction, and restriction. Endomyocardial biopsy can also be useful in diagnosing restrictive cardiomyopathy.

CONGENITAL ABNORMALITIES

Congenital absence of the pericardium is usually partial but can be complete. It is most common on the left side and is more frequent in males. Associated congenital cardiac defects include atrial septal defect, a bicuspid aortic valve, and pulmonary malformations. Defects on the right side can lead to cardiac herniation. Patients can present with chest pain, syncope, or death. The electrocardiogram can show a right bundle branch block. The pericardial defect can be appreciated on CT or MRI. The treatment of a partial defect is total pericardiectomy or patch closure with PTFE or bovine pericardium. Total pericardial absence is usually asymptomatic and is found incidentally.

Figure 86-2. The jugular venous pulse waveform.

Pericardial cysts are rare benign cysts that generally measure 1 to 15 cm in size. They are most commonly found at the right cardiophrenic angle and are asymptomatic. Patients may present with mediastinal compression and respiratory symptoms. The differential diagnosis includes a Morgagni hernia, lipoma, mediastinal tumor, or bronchogenic cyst. CT scans are used to confirm the location and relationship to surrounding structures. The cyst is excised if the patient is symptomatic, or the diagnosis is unclear.

ACUTE PERICARDITIS

Acute pericarditis is an inflammatory process that has involved the pericardium for less than 2 weeks (Table 86-1). Patients often present with a 3- to 7-day prodrome of low-grade fevers, malaise, and muscle aches. Acute pericarditis occurs in 5% of those who present to the emergency department with nonischemic chest pain¹⁰ and in 1% of those with ST elevation.¹¹ It is important to distinguish pericarditis from the chest pain of an acute myocardial infarction. Acute pericarditis usually causes sharp, pleuritic pain that can last several days. The pain most commonly radiates to the trapezius ridge and is improved by leaning forward. Patients can present with shortness of breath, a nonproductive cough, and clear lung fields. The differential diagnosis also includes aortic dissection and pneumothorax. On physical examination, a friction rub may be heard and is sometimes intermittent. The classic friction rub has three components during systole, early diastolic filling, and atrial contraction.

ETIOLOGY

Table 86-1 Causes of Pericarditis

Idiopathic
Infectious
Neoplastic
Hemopericardium
Blunt and penetrating trauma
Postcardiac surgery
Aortic dissection
Autoimmune and inflammatory
Connective tissue disorders
Postmyocardial infarction
Medication induced
Miscellaneous
Radiation induced
Hypothyroidism
Uremic

3 The electrocardiogram is important in the diagnosis and classically shows diffuse ST elevations without Q waves or T-wave inversion. PR depression can also be seen. There is a four-stage progression in the changes seen on EKG with diffuse ST elevations followed by normalization of ST segments with flattening of T waves. The EKG then evolves with T-wave inversions prior to normalization of the EKG. Pericarditis and associated myocarditis can cause elevations in creatinine kinase and troponin I.¹² The minimal workup should include an EKG, complete blood count, cultures, chemistry profile, and antibody titres for collagen diseases.

Idiopathic and Viral Pericarditis

Idiopathic causes of pericarditis are the second most common after neoplastic disease. The majority are likely viral although routine testing is not usually performed. A virus is only identified in 15% to 20% of cases with the most common being Coxsackievirus, echovirus, adenovirus, influenza, and cytomegalovirus. Patients present with chest pain, malaise, and fever and often have an elevated erythrocyte sedimentation rate. The episode is self-limited in 70% to 90% of cases.¹⁰ Initial treatment is with nonsteroidal anti-inflammatory drugs (NSAIDs). There is a 15% to 30% relapse rate at which point specific causes such as autoimmune disorders should be investigated.^{10,13} A repeat course of NSAIDs, colchicine, or steroids is generally successful. Pericardiectomy is recommended if the patient unresponsive to medical treatment or constriction develops.

Acquired Immunodeficiency Syndrome

A pericardial effusion develops in up to 20% of patients with HIV and is usually a poor prognostic sign.¹⁴ This may be partly due to a generalized capillary leak syndrome as well as increased cytokine expression seen in the more advanced stages of HIV. Other contributing factors include tubercular and mycobacterial infections, lymphoma, Kaposi's, or congestive heart failure. The majority are idiopathic and do not require further therapy if asymptomatic. Symptomatic effusions are drained.

Tuberculous Pericarditis

Tuberculous pericarditis occurs in 1% to 8% of patients.¹⁵ In immunocompromised patients infection by *Mycobacterium avium* or *Mycobacterium intracellulare* can lead to pericarditis. The incidence of tuberculous pericarditis has decreased although it continues to be a significant issue in immunocompromised patients, particularly HIV patients in Africa. Patients present with fever, night sweats, cough, dyspnea, and weight loss. While infection usually results from hematogenous spread, it can also extend directly from lymph nodes or through lymphatics. Pericardial changes occur in four stages including fibrinous, effusive, fibrous, and constrictive fibrous stages. Making the diagnosis from pericardial fluid alone is rare. Pericardial biopsy with acid fast staining provides the diagnosis 80% to 90% of the time. Treatment includes multidrug antitubercular therapy and pericardiocentesis. Steroids have not been shown to be beneficial for mortality or progression to constriction but leads to a faster resolution of symptoms and reaccumulation.¹⁶ If patients present with late constriction, pericardiectomy may be required.

Purulent Pericarditis

Bacteria can be introduced into the pericardial space by direct injury, pneumonia, extension from head and neck infections, or hematogenous and lymphatic spread. Patients present with chest pain, fever, and leukocytosis. The most common organisms in adults are staphylococcus, pneumococcus, and streptococcus. Purulent pericarditis can evolve rapidly into tamponade and can be confused with septic shock. Fungal infections are less common, but immunocompromised patients and drug addicts are at greater risk. Pericardial fluid in purulent pericarditis has low glucose, high protein, and elevated LDH and neutrophils. An air–fluid level may be seen on chest radiograph with gas-producing organisms. Treatment includes antibiotics and drainage. Surgical drainage may be needed for thick fluid or refractory effusions. The prognosis for purulent pericarditis is poor with a survival of 30%.^{10,17}

Uremic Pericarditis

Fifty percent of patients with untreated renal disease develop pericarditis. The incidence is decreased to approximately 20% in patients on hemodialysis. The exact cause is unknown but is not directly related to the BUN or creatinine. Other possible etiologies include hypercalcemia, viral infection, and autoimmune disease. Chest pain is usually less common, and the large effusions accumulate gradually. Treatment includes more intensive dialysis, NSAIDs, and steroids. The fluid is generally bloody and care should be taken in heparinizing these patients for dialysis. If patients develop tamponade or the effusion is unresponsive, pericardiocentesis or surgical drainage is performed.

Vasculitis, Connective Tissue Disease, and Drugs

Pericarditis can result from a variety of vasculitic and connective tissue diseases including rheumatoid arthritis, Wegener granulomatosis, rheumatic fever, lupus, scleroderma, Reiter syndrome, Behcet disease, dermatomyositis, polyarteritis nodosa, dermatomyositis, sarcoidosis, and amyloidosis. Treatment includes management of the underlying disease process and NSAIDs. Pericardiocentesis is performed if necessary. Several medications can also lead to pericarditis including warfarin, hydralazine, isoniazid, procainamide, phenytoin, dantrolene, cromolyn, and methysergide.

Dressler and Postpericardiotomy Syndrome

Pericarditis can occur following acute myocardial infarction in 3% to 5%.¹⁸ Pericarditis can develop early in the first 1 to 3 days particularly with transmural infarction. Forty percent of large Q-wave infarctions cause pericardial inflammation although the incidence is decreasing with the use of thrombolytics and early revascularization. Patients are usually asymptomatic and are found to have a pericardial rub on examination although they can present with pleuritic chest pain. Treatment is usually with NSAIDs. Steroids can prevent conversion of infarcted myocardium to scar leading to greater thinning and risk of rupture.^{19,20}

Patients can also present with pericarditis 1 week to a few months after a myocardial infarction with a friction rub, typical EKG changes, and chest pain although the incidence has decreased with increased revascularization. Pericardial inflammation is thought to be from an autoimmune reaction to myocardial cells.²⁰ Similar symptoms can also occur after cardiac surgery, blunt trauma, and pacemaker placement. Patients can develop a pericardial effusion and even tamponade. Treatment includes NSAIDs and colchicine for 2 to 3 weeks and occasionally steroids. The syndrome is usually self-limited.

Radiation-Induced Pericarditis

Pericarditis can result from mediastinal and thoracic radiation for cancer including lymphoma and breast carcinoma and is related to the dosage delivered. With modern techniques, the incidence is 2% but can be as high as 20% if the entire pericardium is treated. Patients may develop chest pain and fever.²⁰ Symptoms are usually self-limited, and tamponade is rare. Delayed symptoms can develop years later and can result in pericardial constriction. Due to the history of malignancy, the etiology can be confused with a malignant effusion. If pericardial constriction develops, the treatment is pericardiectomy although the mortality is higher than for other etiologies.

PERICARDIAL EFFUSION AND TAMPONADE

Any of the etiologies mentioned above for pericarditis can also lead to a pericardial effusion. Other causes include blunt or penetrating trauma, retrograde bleeding from an aortic dissection, and a transudative effusion from congestive heart failure. Effusions due to a bacterial or fungal infection, HIV,

or malignancy have a higher incidence of progressing to tamponade. Twenty percent of large symptomatic effusions of unknown cause are due to an undiagnosed cancer.²¹

4 Normally there is only a small reserve volume before pericardial fluid causes significant cardiac compression and prevents adequate cardiac filling. The hemodynamic significance of a pericardial effusion depends on the volume and the rate of accumulation. The compensatory adrenergic response to a pericardial effusion leads to tachycardia and increased contractility, and patients on beta blockers are less likely to compensate. Tamponade usually occurs when filling pressures reach 15 to 20 mm Hg although tamponade can occur at lower pressures in conditions where blood volume is reduced including dialysis, with diuretic therapy, and bleeding. Cardiac pressures become elevated and are most closely equalized during inspiration. Tamponade generally affects right heart filling first which then leads to underfilling of the left heart.²²

Patients may present with dyspnea, tachycardia, and diaphoresis. The three classic signs of Beck triad are hypotension, jugular venous distension, and muffled heart sounds although each may be absent in patients with tamponade.²³ Symptoms can be confused with right heart failure and pulmonary embolus. The jugular waveform changes characteristically with loss of the y descent.²⁴ Since the total heart volume is fixed in tamponade, blood only enters the heart when blood leaves. The y descent represents opening of the tricuspid valve and is lost since no blood is ejected from the heart. Pulsus paradoxus is also noted with a fall in the systolic blood pressure of greater than 10 mm Hg with inspiration. Pulsus paradoxus is absent in left ventricular dysfunction, atrial septal defect, positive-pressure ventilation, aortic insufficiency, and regional tamponade. The EKG shows variation in the morphology of every other QRS complex, or electrical alternans, due to swinging of the heart in the pericardial effusion (Fig. 86-3). Chest radiograph shows an enlarged, rounded cardiac silhouette, and the pericardial fat pad sign is seen when the pericardial fat is separated from the heart by the effusion.

Echocardiography is the most useful test in diagnosing pericardial effusion and tamponade. Signs of tamponade include early diastolic right ventricular and right atrial collapse (Fig. 86-4) and distension of the cava that does not diminish with inspiration. Doppler is useful in evaluating blood flow and shows exaggerated respiratory variation with an increase with inspiration on the right and decrease on the left side of the heart. Echocardiography is also useful in identifying localized atrial compression which can lead to tamponade with the other changes described above.

Figure 86-3. The 12-lead EKG shows electrical alternans with variation in the morphology of every other QRS complex in a patient with a large pericardial effusion. (From Joffe II, Jacobs LE, Kotler MN. Pericardial tamponade. *Circulation* 1996;94:2667, with permission.)

Figure 86-4. The echocardiogram shows a large pericardial effusion with diastolic right atrial collapse (*arrow*). (From Joffe II, Jacobs LE, Kotler MN. Pericardial tamponade. *Circulation* 1996;94:2667, with permission.)

If there are significant hemodynamic changes, emergent pericardiocentesis should be performed. Intravenous fluid and inotropes can temporize the hypotension but should not delay pericardiocentesis. If the effusion is loculated or contains blood clots, open drainage may be necessary. There should be a higher suspicion for tamponade in situations involving bleeding, bacterial or tuberculous pericarditis, or an acute or increasing moderate-to-large effusion. The approach to a patient with a large pericardial effusion is outlined in [Algorithm 86-1](#).

Postoperative Cardiac Tamponade

5 Postoperative tamponade should always be in the differential diagnosis with low cardiac output after cardiac surgery. Patients may have rising filling pressures, hypotension, and decreased urine and cardiac output. Mediastinal chest tube output may increase or abruptly stop. Hypovolemia during the postoperative period can limit the increase in filling pressures. Pulsus paradoxus may also be masked by positive pressure ventilation. On chest radiograph, the cardiac silhouette is enlarged. In the postoperative cardiac patient, the epicardial pacing wires may move farther from the pericardium with increasing tamponade on chest films. Tamponade can result from relatively small amounts of blood with localized atrial compression from blood clots. There should be a low threshold for reexploration which also provides a definitive diagnosis. Patients can also present with delayed tamponade after being started on anticoagulants.

PERICARDIAL CONSTRICTION

Constriction develops when the heart becomes constrained by a fibrotic pericardium. The process can progress over years, and the most common causes in the developed world are radiation treatment, postsurgical changes, and idiopathic. Tuberculosis was the most common cause before antitubercular drug therapy. Other causes include amyloidosis, scleroderma, sarcoidosis, hemochromatosis, and malignant disease. Patients develop signs and symptoms of right heart failure due to obstruction of the right ventricular outflow tract including hepatomegaly, ascites, and peripheral edema. Patients can also have dyspnea, pleural effusions, fatigue, and weight loss. On physical examination, a pericardial knock, or a loud third heart sound, can be heard which corresponds to the abrupt cessation of diastolic filling. Kussmaul sign is increased jugular venous distension with inspiration. Atrial fibrillation or flutter is present in up to 25% of patients, and tricuspid regurgitation is also common.

Pericardial calcification is pathognomonic but is only seen in 40% of cases. Thickened pericardium can be seen on CT or MRI ([Fig. 86-5](#)) although the pericardium was normal in thickness in 18% of patients in one series.²⁵ The normal pericardial thickness is 2 mm on CT and 4 mm on MRI. Echocardiography shows thickened pericardium and a septal bounce due to the abrupt displacement of the septum during early diastole. The ventricles are small with good function. Ventricular filling halts abruptly in diastole due to the limits of the stiff, fibrotic pericardium. There are signs of systemic venous congestion with a distended inferior vena cava. In contrast to tamponade, there is no decrease in early diastolic filling but a sudden decrease in late diastole ([Table 86-2](#)).²⁴ When the myocardium is involved by fibrosis, ventricular dysfunction is present which is associated with a poorer response to

pericardiectomy.

Algorithm 86-1. This algorithm outlines the initial approach to a patient with a large pericardial effusion.

Figure 86-5. **A:** Chest CT shows extensive pericardial calcification. (From Cavendish JJ, Linz PE. Constrictive pericarditis from a severely calcified pericardium. *Circulation* 2005;112(11):e137–e139, with permission.) **B:** Chest CT shows thickening of the pericardium in a patient with constrictive pericarditis. (From Tom CW, Oh JK. A case of transient constrictive pericarditis. *Circulation* 2005;111:e364, with permission.).

On right heart catheterization, the y descent is deeper and more rapid than normal. The right atrial waveform is M- or W-shaped. The right ventricular tracing is described as the square root sign with an early diastolic decrease with a rapid increase and plateau (Fig. 86-6). Pulmonary artery and right ventricular pressures can be moderately elevated, but more severe pulmonary hypertension suggests a different disease process. In addition, hypovolemia can mask these findings, and patients may need to be volume-challenged to see the diagnostic changes.²⁶

6 Distinguishing constrictive pericarditis from restrictive cardiomyopathy can be difficult but is important since the treatment is significantly different (Table 86-3). In restrictive cardiomyopathy, there is no pericardial thickening. Decreased systolic function, mitral regurgitation, and left heart pressures greater than right are more common in restrictive cardiomyopathy. Early diastolic filling is slower. In addition, left and right ventricular pressures move in the same direction on inspiration rather than opposite directions.²⁷

Constrictive pericarditis is generally progressive although it can be transient after cardiac surgery and should be observed for several months. Diuretics with fluid and salt restriction help initially, but pericardiectomy is the only definitive treatment. Tachycardia is a compensatory response, and beta and calcium channel blockers should be avoided.

NEOPLASTIC PERICARDIAL DISEASE

7 Primary tumors of the pericardium are rare and include benign fibromas, hemangiomas, lipomas, lymphangiomas, leiomyomas, and neurofibromas. Malignant pleural tumors include mesothelioma, teratoma, and fibrosarcoma. Surgical resection is therapeutic and diagnostic. Malignancies can also extend directly from the mediastinum, esophagus, and lung. Metastatic disease is the most common cause of pericardial effusion. Cardiac involvement is found in 5% to 10% of patients dying of cancer with 85% of those having pericardial involvement. The most common cancers are lung and breast carcinoma, lymphoma, melanoma, and leukemia. Patients often present with tamponade. The diagnosis is made on echocardiography or CT. Cytology of pericardial fluid is negative in 20% to 50% of cases, and pericardial biopsy may be helpful. Palliation includes sclerosing agents such as tetracycline, radiotherapy, intrapericardial chemotherapy, and catheter drainage.

DIAGNOSIS

Table 86-2 Distinguishing Cardiac Tamponade and Constrictive Pericarditis

	Tamponade	Constriction
Pulsus paradoxus	Usually present	Present in 1/3 of cases
Jugular venous waveform	Absent y descent	Prominent y descent (M or W)
Inspiratory changes in venous pressure	Decrease	Increase (Kussmaul sign)
Equal right and left pressures	Present	Present
“Square root” sign ventricular pressure	Absent	Present

Figure 86-6. A: The right ventricular (RV) pressure tracing shows elevated RV diastolic pressure with the dip-and-plateau waveform known as the “square root sign.” The EKG tracing shows a large P wave indicative of right atrial enlargement. B: The postoperative RV tracing shows normalization of the RV waveform. (From Correa SD, Amsterdam EA. Constrictive pericarditis. *Circulation* 1998;97:806, with permission.)

PERICARDIOCENTESIS

Pericardiocentesis can be diagnostic and therapeutic. Ideally, it should be performed in the catheterization laboratory so the hemodynamic response can be monitored. Normal pericardial fluid is an ultrafiltrate with an LDH 2.4 times serum and protein 0.6 times.²⁸ Uremic fluid is bloody. Rheumatic effusions are high in protein and leukocytes and low in glucose. Cholesterol crystals are seen with myxedema, tuberculosis, and rheumatoid arthritis.

DIAGNOSIS

Table 86-3 Distinguishing Constrictive Pericarditis From Restrictive

Cardiomyopathy

	Restriction	Constriction
Pericardial knock	Absent	Present
Pulsus paradoxus	Absent	Present in 1/3 cases
Thickened pericardium	Absent	Present
Atrial enlargement	Biatrial	Possibly left atrial
Septal bounce	Absent	Present
Equal right and left pressures	Left 3–5 mm Hg > Right	Present
Filling pressures >25 mm Hg	Present	Uncommon
Pulmonary artery SBP >60 mm Hg	Present	Absent
“Square root” sign ventricular pressure	Variable	Present
Prominent y descent	Variable	Present

SBP, systolic blood pressure.

Generally, a 16- to 22-gauge needle is inserted to the left of the xiphoid. The needle is angled at a 45-degree angle toward the left shoulder (Fig. 86-7). An EKG lead may also be attached to the needle to monitor for an injury current, although echocardiography is more commonly used for guidance. There is a 97% success rate with a complication rate of 4.7% (Table 86-4).²⁹ If the effusion is anterior, a parasternal approach is used 1 to 2 cm to the left of the sternum in the fourth or fifth intercostal space. The removal of even a small amount of fluid can lead to significant hemodynamic improvement. For longer-term drainage a catheter can be placed over a guidewire. Pericardiocentesis may not be effective for purulent or bloody effusions that may require open drainage.

Figure 86-7. Pericardiocentesis is performed by inserting a needle to the left of the xiphoid and toward the left shoulder at a 45-degree angle. An EKG lead may be attached to the needle to monitor for Q waves indicating contact with the epicardium.

COMPLICATIONS

Table 86-4 Potential Complications From Pericardiocentesis

Injury to surrounding organs
Liver laceration
Lung (pneumothorax)
Coronary arteries
Myocardium
Arrhythmias
Pulmonary edema from acute left ventricular failure
Recurrence

PERICARDIAL BIOPSY AND SURGICAL DRAINAGE

Pericardial biopsy is useful when pericardiocentesis is nondiagnostic, which is not uncommon in neoplastic and tubercular effusions. This can be approached through a subxiphoid incision, anterior thoracotomy, or thoracoscopically (Fig. 86-8). Open drainage may be useful if the fluid is viscous, including bloody or purulent effusions, or in patients that have recurrent effusions. Loculated effusions may also require open drainage. The subxiphoid approach is better for purulent effusions to prevent contamination of the pleural space. Chronic or malignant effusions can be drained through a pericardial window into the left pleura. Preinduction pericardiocentesis or intravenous fluids may be necessary for patients to tolerate general anesthesia.

Figure 86-8. Open pericardial biopsy or drainage is performed through an upper midline incision. The xiphoid is retracted or removed providing exposure to the pericardium.

RECONSTRUCTION OF THE PERICARDIUM

Generally, the pericardium does not need to be reconstructed after routine opening of the pericardium during cardiac surgery or when resecting portions of the pericardium for adjacent tumors such as a thymoma. Primary pericardial closure is often avoided due to concerns for hemodynamic compromise and perioperative tamponade. Dantas et al. found a temporary, but clinically insignificant, decrease in hemodynamics in a study of 48 patients with primary closure of the pericardium after open heart surgery.³⁰

8 Reconstruction of the pericardium should be considered in cases where a future redo sternotomy is likely such as a bioprosthetic valve that will need to be replaced or a left ventricular assist device that will be removed at the time of transplant. To prevent hemodynamic compromise, the closure should be performed without tension. A biologic mesh implant made of porcine extracellular matrix has been used to prevent adhesions and protect the right ventricle, aorta, and coronary bypass grafts. Reconstruction of the pericardium was also reported in a retrospective study of 222 patients to decrease the incidence of atrial fibrillation.³¹ However, the results of a randomized trial evaluating new-onset postoperative

atrial fibrillation after pericardial reconstruction using extracellular matrix (NCT01247974) have not yet been reported.

Reconstruction of the pericardium is important when there is a risk of cardiac herniation. When resection of the pericardium is required during pneumonectomy due to a central lung tumor or an extrapleural pneumonectomy for mesothelioma, the pericardium should be reconstructed to prevent herniation into the empty hemithorax.³² Cardiac herniation must be quickly recognized if the patient becomes hypotensive postoperatively. The pericardial defect is reconstructed with a 0.1-mm Gore-Tex mesh. The mesh should be fenestrated with small incisions to allow fluid to escape decreasing the risk of tamponade. Reconstruction of the pericardium may also help to prevent inflammatory epicarditis which can lead to constrictive physiology after extrapleural pneumonectomy.³³

PERICARDIECTOMY

Pericardiectomy is most commonly performed for constrictive pericarditis. It can be performed through a median sternotomy or a left anterior thoracotomy in the fifth intercostal space. Anterior thoracotomy allows removal of the pericardium over the left ventricle with minimal manipulation. Femoral cannulation is used if bypass is necessary. Median sternotomy is the most common approach (Fig. 86-9). Cardiopulmonary bypass increases the risk of bleeding and is used when significant cardiac manipulation is needed or the dissection is difficult. The pericardium over the left ventricle is resected first to avoid pulmonary edema from the right ventricle ejecting against a constricted left ventricle. The pericardium is removed from phrenic nerve to phrenic nerve. Some patients have an immediate improvement in hemodynamics and symptoms while others do not improve until weeks or months later. A delayed or incomplete response is thought to be due to an incomplete resection of the visceral pericardium or myocardial atrophy and fibrosis. Left ventricular function returned to normal in 40% of patients.

Perioperative mortality has been reported between 5% and 15% and is due to low cardiac output, sepsis, bleeding, and renal or respiratory failure.³⁴ Seventy percent of mortality is due to low cardiac output. Mortality is directly related to the patient's preoperative status³⁵ and is 1% for New York Heart Association class I to II, 10% for class III, and 46% for class IV.³⁶ Five-year survival is 84%, and 99% of late survivors were class I or II. Patients with constriction due to radiotherapy have a higher mortality which may be due to radiation-induced myocardial injury. Other poor prognostic factors are renal failure, advanced age, pulmonary hypertension, hyponatremia, and reduced cardiac output.^{34,37}

Figure 86-9. Pericardiectomy is most commonly approached through a median sternotomy. **A:** The pericardium is incised, and the fibrous pericardium dissected from the left ventricle. **B:** The heart is retracted to the right so that the pericardium can be resected from phrenic nerve to phrenic nerve.

Chapter 87

Vascular Diagnostics: The Noninvasive Vascular Laboratory

Gregory L. Moneta

Key Points

- 1 Duplex ultrasound consists of a combination of gray-scale imaging and pulse Doppler. Because the speed of sound is relatively constant in tissue, with a pulse Doppler it can be determined when an echo is generated and when it is received. This provides range resolution enabling the operator of the duplex machine to precisely sample and interrogate blood flow at a known location.
 - 2 When a sound wave encounters moving reflectors, such as red blood cells, the frequency of the reflected wave changes from that of the original wave generated by the transducer. This relationship is reflected in the Doppler equation: $f_r - f_o = [(2f_o v)/c] \cos \theta$, Where f_r is the received frequency, f_o is the originating frequency, v is the velocity of the reflector, c is the speed of sound in tissue, and θ is the angle of the incident sound beam with the moving reflectors, the so-called Doppler angle.
 - 3 Arterial Doppler waveforms reflect the resistance of the circulation supplied by the artery being examined. Low resistance circulations such as cerebral and renal circulations have relatively high amounts of diastolic flow whereas high-resistance circulations, such as extremity arteries have little flow at the end of diastole.
 - 4 Carotid stenosis is determined primarily from measurement of peak systolic velocity (PSV) and end-diastolic velocity (EDV) from pulse Doppler waveforms using criteria agreed upon in a national consensus conference.
 - 5 Air plethysmography can be used to display pulse volume waveforms. Pulse volume recordings (PVRs) are obtained with partially inflated blood pressure cuffs that detect volume changes sequentially down a limb. Volume changes beneath the cuffs resulting from the pulse wave result in small pressure changes within the cuffs. These changes are displayed as arterial waveforms with the use of appropriate transducers and provide an overall measure of the arterial circulation in an extremity.
 - 6 The ankle brachial index (ABI) is determined by dividing the higher ipsilateral dorsal pedal or posterior tibial artery pressure by the higher of the two brachial artery systolic pressures and is highly sensitive and specific for documenting the presence or absence of lower extremity arterial occlusive disease.
 - 7 Measurement of ankle pressures after exercise can be used to confirm arterial disease as an etiology for exercise-associated leg pain. Failure of the ankle pressure to drop with exercise along with failure of the ABI to decrease 20% with exercise, combined with a normal resting ABI, substantially rules out arterial insufficiency as an etiology of exercise-induced complaints of leg pain.
 - 8 Duplex ultrasound can detect hemodynamically significant stenosis in abdominal arteries: a PSV in the superior mesenteric artery (SMA) of 275 cm/s or more indicates a $\geq 70\%$ SMA stenosis, a celiac artery PSV of ≥ 200 cm/s indicates a $\geq 70\%$ celiac artery stenosis whereas a ratio of the PSV in a renal artery to that in the aorta (renal-aortic ratio, RAR) of ≥ 3.5 indicates a $\geq 60\%$ diameter-reducing renal artery stenosis.
 - 9 The primary ultrasound diagnostic criterion for diagnosis of venous thrombosis is failure of the vein to collapse with application of pressure with the ultrasound probe.
 - 10 In the upright position, venous reflux stimulated by cuff deflation that lasts > 0.5 to 1 second is indicative of pathologic venous reflux.
-

The noninvasive vascular laboratory provides accurate, safe, and objective evidence of the presence and physiologic significance of vascular disease throughout the body. Two broad categories of testing are

available in the noninvasive vascular laboratory; those based on plethysmographic techniques, and those based on ultrasound-based techniques.

PLETHYSMOGRAPHY

Plethysmographic techniques detect volume changes in limbs that occur in response to arterial and venous disease. The technology can be modified to determine digital pressures and produce pulse waveforms. Examples of plethysmographic techniques include mercury strain gauge plethysmography, air plethysmography (pulse volume recordings [PVRs]), and photoplethysmography.

ULTRASOUND

Ultrasound techniques, in particular duplex ultrasound-based technique, have largely eclipsed plethysmographic techniques. Duplex ultrasound, introduced in 1974, was first applied to carotid arteries. The technique combines information from ultrasound-generated images (B-mode) and Doppler analysis of blood flow direction and velocity, hence the term “duplex.” Duplex ultrasound is currently extensively employed for evaluation of carotid arteries, intra-abdominal arteries and veins and upper and lower extremity arteries and veins. Since inception duplex ultrasound has advanced through: (1) improved B-mode imaging, (2) better low-frequency scan heads permitting deeper penetration of the ultrasound beam from the skin surface, (3) improvements in online computer-based microprocessor software, and (4) perhaps, most importantly, the addition of color flow to the B-mode image.

Color flow superimposes a real-time color image of blood flow onto a standard gray-scale B-mode picture. Returning echoes from stationary tissues generate the B-mode image, whereas those interacting with moving substances (blood) generate a significant enough phase shift that they can be processed separately and color-coded by operator selection to give information on direction and velocity of blood flow according to the magnitude and direction of the Doppler frequency shift. It is color flow, combined with the ability of the current generation of duplex scanners to detect very low blood flow velocities (<5 cm/s), which makes duplex scanning practical on a routine basis throughout the body. Color flow permits more rapid identification of vessels to be examined and is essential for duplex examination of some vessels such as tibial arteries and veins.

BASICS OF DUPLEX ULTRASOUND

An ultrasonic wave is produced in tissue by placing a vibrating source in contact with the tissue. In medical ultrasound the vibrating source is the ultrasound *transducer* contained within the ultrasound *scan head*. The scan head steers and focuses the sound beam arising from the transducer, functions crucial in deriving an ultrasound image from returning echoes.

Ultrasound transducers convert electrical energy into vibrational energy and, conversely, turn vibrational energy of returning echoes into electrical signals that can be analyzed by the software of the duplex machine. The design of the transducer determines the frequency of the vibrations which in turn determines the wavelength of the sound wave produced. The relationship between frequency and wavelength is expressed mathematically as follows:

$$\lambda = c/f \quad (87-1)$$

Where λ is the wavelength, c is the speed of sound in tissue and f is the incident frequency.

The speed of sound in soft tissues averages 1,540 m/s and varies only minimally from this average in soft tissues insonated in clinical applications of duplex ultrasound. The wavelength of the sound beam is the primary determinant of how well the ultrasound beam penetrates the tissue. Because the speed of sound within the tissue is, for all practical purposes, constant (1,540 m/s), the ability of ultrasound to penetrate tissue depends on the frequency of the vibrating source (transducer). As noted above, transducer frequency is determined by the design of the transducer and is thus controlled by the manufacturer of the duplex device. For examination of the carotid artery, transducer frequencies of 5 to 7.5 MHz provide optimal tissue penetration for clinical purposes.

As noted above the term duplex refers to the combination of Doppler and B-mode (“B” stands for “brightness”) ultrasound in the same device. Both types of ultrasound require analysis of reflected

echoes of the original sound beam initially created by placing the ultrasound transducer in contact with the tissue. The B-mode component of the duplex machine analyzes the *strength* (intensity) and *origin* of the reflected echo. The Doppler component analyzes *shifts* in frequency of the original sound wave produced by the transducer that result when the ultrasonic wave encounters moving reflectors.

B-Mode Ultrasound

As a sound wave passes through tissue, its strength moving away from the transducer depends upon the degree to which the beam is attenuated, scattered, and reflected. The strength of the reflected echo depends in part, upon relative differences in acoustic impedance between two different media. Major differences in acoustic impedance result in reflection of a large proportion of the sound beam back to the transducer, whereas small differences result in comparatively little reflection and continued propagation of the beam through the tissue.

In B-mode ultrasound, the strength of the returning echo is reflected in the brightness of the individual pixels comprising the ultrasound image. This is the ultrasound *grayscale* and the resulting image is termed a *grayscale image*. (As we will see below, the primary purpose of the grayscale image in duplex ultrasonography is to aid in properly positioning the Doppler sample volume.)

Very bright pixels represent sites of large differences in acoustic impedance between media, whereas less dramatic differences are represented by proportionally less bright pixels on the B-mode image. Thus gallstones, which differ dramatically in acoustic properties from soft tissue, result in strong echoes and proportionally brighter pixels on an ultrasound image, whereas blood, which differs little from soft tissue in acoustic characteristics, frequently cannot be distinguished from soft tissue in a grayscale image.

The strength of the reflected echo will also be dependent upon the strength of the sound beam at the point of its reflection. Grayscale images do not show the percentage of the beam reflected, but rather represent the absolute strength of the reflected echo arriving back at the transducer. Thus if the sound beam is very weak at the site of its reflection, even areas of significant differences in acoustic impedance will not result in a bright pixel on the ultrasound image.

The strength of the ultrasound beam at any point also depends on the degree to which the beam has been attenuated as it passes through the tissue. Attenuation of a sound wave as it traverses tissue weakens the wave and depends upon the tissue traversed and the frequency of the wave. The frequency of the wave depends upon the frequency of the transducer used to generate the wave (see discussion above and [Equation 87-1](#)). Sound waves resulting from higher-frequency transducers are attenuated more rapidly than those produced with lower-frequency transducers. Higher-frequency transducers therefore provide relatively weak echoes to be reflected from a deep structure and thus a comparatively poor B-mode image compared to a lower frequency transducer.

The linear resolution of an ultrasound image depends upon the ability to focus the beam. Sound beams emanating from high-frequency transducers can be more precisely focused than those from low-frequency transducers and thus provide clearer B-mode images of more superficial structures. Because the carotid artery is superficial, higher-frequency transducers can be used to provide much clearer B-mode images than is possible with deeper vessels such as the aorta, renal, or iliac arteries.

Doppler Ultrasound

In a continuous wave Doppler, a transducer continually emits vibrations into the tissue. Echoes are therefore continually reflected back to the transducer. A transducer cannot, however, simultaneously generate and receive an echo. Continuous wave Doppler therefore must have separate transmitters and receivers to both generate and receive echoes.

1 Duplex devices utilize pulse Doppler. A pulse Doppler uses the same transducer to generate and receive echoes. Because the speed of sound is relatively constant in tissue, with a pulse Doppler it can be determined when an echo is generated and when it is received and therefore it is possible to calculate the depth in the tissue where a reflected echo originated. The *sample volume* of the duplex device is thus determined by specifying from what depth one wishes the pulse Doppler to receive reflected echoes.

The transducer is *gated*, based on the total time from original sound-wave generation to arrival of the reflected echo back at the transducer, to only receive echoes from the specified depth of the sample volume. The desired “position” of the sample volume is determined by the operator of the duplex device from the B-mode image, and in duplex examination of arterial and venous flow corresponds to particular points within the lumen of the vessel examined. Because B-mode images and Doppler

waveforms cannot be generated simultaneously, the technologist must continually update the B-mode image during the course of the examination to insure proper placement of the sample volume.

2 When a sound wave encounters moving reflectors, such as red blood cells, so-called Rayleigh scatters, within the lumen of an artery or vein, the frequency of the reflected wave changes from that of the original wave generated by the transducer. Velocity is a vector with both speed and direction therefore, the magnitude of the frequency shift depends upon the velocity of the moving reflectors and their angle with the incident sound beam. Because the frequency of the original sound wave is known, and the frequency of the received echo can be determined by the software of the duplex machine, the velocity of the moving reflectors (red blood cells) can be calculated provided the angle of the incident sound beam with the moving reflectors is also known. This relationship is reflected in the *Doppler equation*:

$$f_r - f_o = [(2f_o v)/c] \cos \theta \quad (87-2)$$

Where f_r is the received frequency, f_o is the originating frequency, v is the velocity of the reflector, c is the speed of sound in tissue, and θ is the angle of the incident sound beam with the moving reflectors, the so-called *Doppler angle*.

A Doppler angle of 0 degrees is ideal for velocity calculations as the cosign of 0 is 1 and measured reflected velocity changes are therefore 100% of what actually occurred. However 0-degree Doppler angles are difficult to obtain as it is not generally possible to look directly down the lumen of a vessel from a percutaneous approach. Therefore to solve the Doppler equation for the velocity of the moving reflectors, the Doppler angle must be known. To standardize the results of duplex scanning, it has been traditionally recommended that examinations be conducted as close as possible to a Doppler angle of 60 degrees. The cosign of 60 is 0.5, therefore at this angle the measured reflected velocity is half the actual reflected velocity. Errors in velocity calculations secondary to misreading of the Doppler angle are small as a percentage of the true velocity at ≤ 60 degrees as cosigns vary comparatively little with incremental changes in angle below 60 degrees. When the Doppler angle approaches 70 degrees, changes in the cosign of the angle become more pronounced with incremental increases in angle, and errors in velocity calculations secondary to improper angle measurement become much more significant. Small errors in determining the Doppler angle when the angle of insonation is < 60 degrees have little overall impact on the calculation of the velocity of the moving red cells. Indeed, Doppler angles from 45 to 60 degrees are acceptable for most clinical studies. Most often an angle of 60 degrees can be easily obtained in carotid artery and extremity artery duplex examinations and, in line with traditional teaching, 60 degrees is chosen whenever possible as the Doppler angle in such studies. In examination of intra-abdominal vessels it may be much more difficult to adhere to a 60-degree angle.

As noted above, pulse Doppler both transmits and receives echoes with the same transducer. This dual function places limits on the frequencies that can be displayed in the spectral waveform. The maximum frequency that can be displayed is half the pulse-transmitting frequency or pulse-repetition frequency (PRF), and is known as the *Nyquist limit*. If frequencies are encountered that exceed the Nyquist limit, they are flipped and appear on the reverse-flow side of the spectrum. This is termed *aliasing*. If aliasing is encountered, the PRF should be increased to increase the Nyquist limit. The PRF can be adjusted by changing the scale displayed on the right side of the spectral waveform or by adjusting the baseline. If aliasing still occurs, the operator should consider switching to a lower frequency transducer or to the use of a continuous-wave Doppler. A continuous-wave Doppler is not affected by aliasing.

Color Flow

A color flow image is produced by assigning color to Doppler shifts. Returning echoes that are not Doppler shifted are shown in grayscale. The net result is what appears to be color pasted or superimposed on a grayscale image. This pasting process can in effect obscure the edges of the grayscale image resulting in obfuscation of the true lumen of the grayscale image limiting somewhat the accuracy of color images to define stenosis. The hue and intensity of the color are determined by the direction and magnitude of the Doppler shifts. The technologist can adjust the color settings as desired. Varying shades of red and blue are generally used to distinguish flow toward or away from the transducer. By convention, red is most often assigned to arterial flow and blue to venous flow.

When the Doppler angle is 90 degrees, there is no Doppler shift. When this occurs, the assigned color is black and corresponds to the horizontal black bar serving as the baseline on the color scale that appears on the right side of a color flow image (Fig. 87-1). Aliasing can be readily recognized on a color flow image as a mosaic pattern or as a transition from red-to-blue or blue-to-red without an intervening

black line. In areas of actual reverse flow, the blue and red colors are separated by a black border. Just as with pulsed Doppler, color aliasing can be reduced by increasing the PRF. This is often quite important, as an extensive mosaic pattern can obscure clear visualization of a stenotic site.

Power Doppler is a variant of color Doppler. Power Doppler, however, assigns no direction of flow to the color image and velocity information is not calculated. Any detected Doppler shift is colorized without consideration of the direction of the Doppler shift or the magnitude of the Doppler shift. It is therefore not subject to aliasing or affected by Doppler angle. Its principle utility lies in the ability to detect blood moving at very low velocity and in outlining the course of tortuous vessels. It can be quite useful in detecting flow in small distal veins and flow in arteries distal to a very high-grade stenosis.

It is tempting to try a direct estimate of the severity of a stenosis from the color flow image. However as discussed above such estimates are probably less accurate than measurements of stenosis derived from spectral analysis. Color serves primarily as a guide in locating the vessels and selecting specific sites for examination with the pulse Doppler. The absence of color can indicate extensive mural calcification and difficulty in obtaining a pulse Doppler waveform.

Figure 87-1. Flow separation with reverse flow along the wall of the carotid bulb as indicated by direct transition from blue to red with an intervening black line is a normal finding and indicates an artery without significant plaque.

Carotid and Vertebral Arteries

The vascular laboratory began with assessing internal carotid artery (ICA) stenosis. Doppler diagnosis of ICA stenosis, and arterial stenosis in general is based on duplex ultrasound and focuses on three areas, the prestenotic region, the stenosis itself and the poststenotic region. Detecting carotid stenosis involves a combination of spectral analysis, color and grayscale imaging and, in selected cases, power Doppler. The primary interest is in the detection of increased flow velocities within the area of suspected stenosis and therefore in most cases spectral analysis dominates in the detection of carotid stenosis. The exception is in distinguishing ICA occlusion from a very high-grade stenosis where color flow or power Doppler flow can identify very low flow in the area of the stenosis or distal to the stenosis that may not be detected by pulse Doppler.

In all cases, the pulsed Doppler and color flow findings should be crosschecked for concordance. If there is disagreement between the impression obtained with color and pulsed Doppler examinations (i.e., color Doppler suggests high-grade stenosis but velocities are only moderately elevated), the findings of both should be reviewed to resolve the discrepancy.

Common Carotid Artery (CCA) Waveforms

3 In the majority of cases, carotid stenosis or occlusion occurs in the proximal ICA at or just beyond the carotid bifurcation. A normal ICA waveform reflects the low resistance of the cerebral circulation with high flow at the end of the diastolic component of the waveform. In the presence of a distal ICA occlusion resistance to flow increases and there is decreased flow in diastole ([Fig. 87-2A,B](#)). The external carotid artery (ECA) supplies the relatively higher-resistance circulation of the scalp and face and therefore has a low-end diastolic flow component ([Fig. 87-2C](#)). The common carotid artery waveform reflects the fact that normally 80% of CCA flow is directed to the ICA. CCA end-diastolic flow is therefore generally well above baseline and exceeds ECA diastolic flow ([Fig. 87-2D](#)). In the presence of a very high-grade ICA stenosis or ICA occlusion, outflow is primarily through the higher-resistance

external carotid circulation. The CCA waveform then takes on the high-flow resistance characteristics of an ECA, with flow to zero, or nearly zero, in end diastole (Fig. 87-3).¹ In addition, the PSV and the overall flow velocity may be substantially lower than normal because of reduced carotid artery flow. By observing these changes in the CCA, one can reliably predict the presence of high-grade stenosis or occlusion of the ICA.

Figure 87-2. A: A normal internal carotid artery (ICA) waveform with high diastolic flow (*white arrow*) reflecting the low resistance of the cerebral circulation. B: Absence of ICA diastolic flow (*red arrow*) indicates more distal occlusion or severe stenosis of the extracranial or intracranial ICA. C: Normal external carotid artery waveform. The external carotid artery has low diastolic flow reflecting the high resistance circulation of the scalp and face. D: Normal common carotid artery waveform. The common carotid artery waveform has diastolic flow well above the baseline as the majority of flow is directed to the low resistance internal carotid artery circulation.

Figure 87-3. In a patient with internal carotid occlusion common carotid artery (CCA) diastolic flow approaches 0 (*arrows*) as CCA flow is now routed to the high resistance external carotid circulation.

The CCA *contralateral* to an ICA stenosis or occlusion may demonstrate an increased flow velocity with particular elevation of the velocity at the end of diastole; the so-called end-diastolic velocity (EDV). These changes represent a compensatory increase in blood flow volume in the nonobstructed ICA in response to reduced contribution to cerebral perfusion from the opposite high-grade stenotic or occluded ICA. This compensatory hemodynamic change can be substantial and flow velocities may be artificially elevated on the side with compensatory high-volume flow giving a false impression of the presence of a stenosis or a higher degree of stenosis than is actually present.²

In the presence of a significant stenosis at the origin of a CCA or the innominate artery, the ipsilateral CCA waveform may be dampened, with low overall peak systolic velocities (PSVs) and EDVs and a slower rise to peak systole when compared with the contralateral CCA waveform and potentially reverse flow in the ICA (Fig. 87-4A,B). The CCA flow changes seen with proximal stenosis are also important in the diagnosis of ICA stenosis because the overall reduction in flow velocity may artificially lower velocities in an ipsilateral ICA stenosis, leading to underestimation of the severity of ICA stenosis. In some cases of proximal CCA or innominate artery stenosis, the stenotic lesion may not be accessible to direct insonation by the duplex scanner. In such cases, a stenotic lesion can be suspected as the ipsilateral CCA waveform will often exhibit poststenotic turbulence low in the neck, reflecting disturbed flow distal to the more proximal stenosis.

ICA Waveforms

As noted above, the normal ICA spectral waveform is indicative of high flow in a low-resistant circulation. The systolic upstroke is rapid, PSV is <125 cm/s, and flow is maintained throughout diastole (Fig. 87-2A).³ In the absence of plaque there is generally a clear spectral window under the outline of the spectral waveform as there is little turbulent flow. The presence of color shifts, indicating high-velocity flow, and color mosaics, indicating poststenotic turbulence, aids in selecting potential areas for examination with the pulsed Doppler.

Hemodynamic quantification of the severity of ICA stenosis is primarily achieved by analysis of Doppler spectral waveforms and measurements of peak systolic and EDV or comparison of PSVs in the ICA to those in the CCA just proximal to the carotid bifurcation, ICA/CCA ratio. As a stenosis develops, the PSV first becomes elevated. PSV is the primary measure of stenosis severity. EDV lags behind, relatively speaking, as stenosis severity progresses but rises rapidly as the stenosis becomes severe (diameter reductions of $\geq 60\%$). Thus, elevation of EDV is a good marker for high-grade stenosis (Fig. 87-5).⁴ The ICA/CCA ratio is also a very important measure of stenosis severity.⁵ Because it is a ratio, it compensates for abnormally high- and low-flow states that may skew the PSV and EDV upward or downward.

To accurately measure flow velocity, the sample volume must be placed within the area of greatest stenosis. Color flow imaging has demonstrated that the orientation of the stenotic jet within a stenosis is frequently not along the longitudinal axis of the vessel. This finding has resulted in controversy with

regard to the proper technique of obtaining velocity waveforms at sites of stenosis. In areas of mild to moderate stenosis, use of a Doppler angle of 60 degrees to the long axis of the vessel is recommended. However, in areas of more severe stenosis and/or wall abnormalities, the Doppler angle of 60 degrees should be defined by the long axis of the stenotic flow jet, as demonstrated by color flow.

Figure 87-4. A and B: In the presence of innominate artery very high-grade stenosis or occlusion the common carotid artery (CCA) waveform will be blunted with a decreased amplitude and slowed upstroke (**A**), and there can be actually reverse flow (**B**) in the ipsilateral internal carotid artery (ICA).

Figure 87-5. Internal carotid artery (ICA) waveform from the site of a $>80\%$ ICA stenosis. Both peak systolic and end-diastolic velocities are very elevated.

The sample volume size should be kept as small as possible, usually 1.5 mm, to detect discrete changes in flow velocity. This is important as the highest velocities may be localized to a small area in the flow stream that emanates from the stenosis. A large sample volume that incorporates flow from many points within the vessel in the generation of the spectral waveform may give the false impression of disturbed flow, potentially leading to the misdiagnosis of moderate disease in an otherwise normal vessel. In practice, the sonographer, having identified the stenosis, gently moves a small sample volume around until the point of highest velocity is found.

Damping of spectral Doppler waveforms may be seen in the region distal to the carotid stenosis when the lesion is severe enough to be flow reducing. The most common abnormality seen distal to a carotid stenosis is spectral broadening caused by disturbed blood flow or turbulence. At best, poststenotic flow disturbance is a qualitative measure of arterial stenosis; nevertheless, its detection is important. With proper gain settings, “fill-in” of the Doppler spectral waveform generally indicates the presence of carotid stenosis with diameter reduction of at least 50%. However, this level of disturbed flow occasionally can be seen with nonstenotic disease. Diagnostically, the most significant poststenotic flow

disturbance produces a simultaneous forward and reverse spectral Doppler signal, accompanied by poor definition of the upper spectral border. Such disturbed flow implies the presence of severe carotid stenosis. Severely disturbed flow distal to a highly calcified plaque may be the only substantial evidence for the presence of clinically significant stenosis if calcification prevents direct insonation of the stenosis.

Figure 87-6. Bony landmarks of the vertebral bodies (*arrow*) mark the course of the vertebral artery.

Vertebral Artery

On rare occasions, a stenosis may be found in the cervical portion of the vertebral artery associated with cervical osteoarthritis. However, the origin of the vertebral artery from the subclavian artery is by far the most common site of disease in the vertebral artery. The vertebral artery origin lies deep in the base of the neck and may be difficult to access with ultrasound. Mean vertebral artery diameter is about 4 mm but the vertebral arteries are frequently asymmetric in size with one, most commonly the left, being larger than the right.

The vertebral artery is most commonly interrogated with ultrasound further distally in the neck, from an anteroposterior window, as it threads through the transverse processes of the cervical spine. The vertebral bodies serve as a reference to insure the vertebral artery is actually under examination ([Fig. 87-6](#)). The artery is usually seen deeper but adjacent to the vertebral vein. Color Doppler is helpful to locate the vessel. A spectral waveform from the vertebral artery in the mid-neck provides information about direction of flow, waveform shape, and velocity but does not rule out disease at the origin. The normal vertebral artery waveform is similar to that of the ICA with normal PSVs reported to be 20 to 40 cm/s.⁶ Velocities up to 80 cm/s are, however, frequently seen without apparent clinical importance and may represent collateral flow through a dominant vertebral artery, or a small but disease-free, vertebral artery. Evaluation of disturbed flow distally may help determine which elevated velocities are associated with a vertebral artery stenosis and which are not. Velocity patterns are usually similar in the two vertebral arteries but systolic and diastolic velocities may differ if vertebral artery diameters are asymmetric. For this reason if there is concern for stenosis based on an elevated peak systolic velocity (PSV) in a vertebral artery, recording of vertebral artery diameters is important.

Flow in the vertebral artery is normally antegrade with a rapid upstroke and continuous diastolic flow. In cases of anatomic subclavian steal, color flow provides an important initial clue to the diagnosis as flow in the artery will be retrograde in the same direction as the vein. Spectral Doppler must still be used to verify arterial flow and will demonstrate reverse or bidirectional flow in cases of subclavian steal. Depending on the degree of subclavian stenosis the vertebral artery flow may be reversed or biphasic, with flow above and below the baseline ([Fig. 87-7A,B](#)). End-diastolic flow will be zero or near zero reflecting the high resistance of the peripheral arm circulation rather than low-resistance cerebral circulation. High-resistance vertebral artery flow may also be seen with antegrade flow and like the situation for the ICA may represent distal stenosis or occlusion of the vertebral artery or an atretic or hypoplastic distal vessel.

Figure 87-7. A and B: Both reverse vertebral artery flow (A), and vertebral flow both above and below the baseline (B) indicate a proximal innominate or subclavian artery stenosis.

External Carotid Artery

The ECA is smaller in diameter than the ICA at the level of the carotid bulb but similar in diameter beyond the bulb. It has little clinical significance in most cases but can serve as an important source of collateral flow to the brain in cases of ICA very high-grade stenosis, or occlusion. The ECA may also serve in such cases as a conduit for emboli to the brain; the so-called carotid stump syndrome.⁷

The ECA waveform has a sharp upstroke, a prominent dichroitic wave in late systole or early diastole, and velocity that is near or at the zero base line in end-diastole. The PSV of the ECA is normally higher than the ICA. The ECA may adopt the characteristics of the ICA in end-diastole as the resistance in the face and scalp decreases with temperature change and/or in the presence of disease. In cases of common carotid occlusion with preservation of patency of the carotid bulb, reverse flow in the ECA can provide antegrade flow in the ICA maintaining patency of the ICA even with CCA occlusion.

Classifying Carotid Stenosis

Duplex criteria for quantifying carotid artery stenosis were developed by comparing duplex-derived spectral waveforms and contrast arteriograms. Duplex-derived *categories* of stenosis are relatively broad. Sensitivities and specificities for spectral analysis of duplex-derived waveforms for detecting an ICA stenosis of >50% to 99% are between 90% and 95%. There are numerous spectral criteria for classifying ICA stenosis. Some focus on *categories* of stenosis, whereas others focus on *threshold levels* of stenosis.

One of the most widely accepted classification schemes for categories for ICA stenosis was developed at the University of Washington under the direction of Dr. Eugene Strandness. These criteria were useful in the study of the natural history of carotid atherosclerosis and in clinical practice. In the University of Washington system, velocity waveform analysis and spectral criteria were used to classify ICA angiographic stenosis as normal, 1% to 15%, 16% to 49%, 50% to 79%, and 80% to 99% stenosis and occlusion. Prospective validation of these criteria has demonstrated an overall agreement of 82% with contrast angiography. The ability of the criteria to detect carotid disease is 99% sensitive and the ability of the criteria to recognize normal arteries is 84% specific.³

Criteria for detecting carotid artery stenosis scanning have undergone reevaluation to remain relevant to current clinical practice. This reevaluation was stimulated by the randomized trials testing the efficacy of carotid endarterectomy (CEA) that took place over the last two decades (Table 87-1).⁸⁻¹² The trials had a profound impact on validating the indications for CEA in patients with carotid bifurcation atherosclerosis. The trials identified significant benefit, in terms of stroke reduction, for CEA in patients with specific levels of ICA stenosis. In particular, patients with symptomatic ICA stenosis >70% to 99%

had dramatic benefit from CEA, whereas patients with symptomatic ICA stenosis between 50% and 69% and patients with asymptomatic ICA stenosis between 60% and 99% also benefited, albeit to a lesser extent, from CEA.

In the North American trials of CEA, ICA stenosis was calculated from arteriograms by comparing the diameter of the minimal residual lumen to the diameter of the distal cervical ICA.¹³ The University of Washington duplex criteria for categories of stenosis pre-existed the endarterectomy trials and were developed comparing the diameter of the residual ICA lumen at its narrowest point with an estimate of the diameter of the ICA bulb if it were free of atherosclerosis. Because the bulb has a greater diameter than the distal ICA, the two methods of measurement do not give the same calculated percentage of angiographic stenosis for the same lesion. Calculations of angiographic stenosis using the distal ICA as the reference vessel result in lower calculated stenosis percentages than calculations using the bulb as the reference site. This effect is particularly striking for modest lesions.

Table 87-1 Major Randomized Trials Assessing Efficacy of Carotid Endarterectomy

Asymptomatic Carotid Surgery Trial (ACST) ¹²

In a review of 1,001 internal carotid angiograms, 34% of the ICAs were classified as stenosis of 70% to 99% using the ICA bulb as the reference vessel. In contrast, when the distal cervical ICA was used as the reference site, only 16% of the ICAs were classified as 70% to 99% stenosis.¹⁴ More than 99% of the distal ICA-based calculations of stenosis were less than bulb-based calculations. Thus, the duplex stenosis criteria using the bulb as the reference vessel are not and were not directly applicable to the results of the clinical trials.

Current Criteria for ICA Stenosis

Since the randomized CEA trials were completed, additional duplex criteria were developed comparing duplex scans to angiographic ICA stenosis using the distal ICA as the reference vessel in calculating angiographic stenosis. Such criteria are considered more useful by many in selection of patients for carotid intervention because they are directly applicable to the threshold levels of carotid stenosis addressed in the CEA trials.

The initial studies addressing the issue of duplex criteria relevant to the CEA trials were performed at the Oregon Health & Science University (OHSU)^{5,15} with subsequent publications from many different institutions, with many different proposed criteria for identification of clinically relevant threshold levels of ICA stenosis.¹⁶⁻²¹

Recognizing that duplex criteria from different centers differed for the threshold levels of angiographic stenosis determined by the CEA trials, a panel of authorities from a variety of medical specialties assembled to review the carotid ultrasound literature. The panel developed a consensus regarding the key components of the carotid ultrasound examination and reasonable criteria for stratification of ICA stenosis.²²

The consensus committee recommended that all carotid examinations be performed with grayscale imaging, color Doppler, and spectral Doppler. Examinations should be performed by a credentialed vascular technologist in accordance with the standards of an accrediting body. Doppler waveforms should be measured with an insonation angle as close to 60 degrees as possible but not exceeding 60 degrees, and the sample volumes should be placed within the area of maximal stenosis. The panelists recommended the consistent use of relatively broad diagnostic strata to estimate the degree of ICA stenosis. The panel also concluded that Doppler is relatively inaccurate for subcategorizing ICA stenosis <50%, and recommended that these lesions be reported under a single category as <50% stenosis, and that subcategories for minor degrees of stenosis not be used.

4 The consensus panel noted that PSV is easy to obtain. However, data suggest reproducibility of PSV,

even among experienced vascular technologists, has sufficient problems that PSVs should not be used as a continuous variable in clinical carotid duplex scanning. Even so, the degree of stenosis estimated by ICA PSV and the degree of narrowing of the ICA lumen seen on grayscale and color Doppler should correlate with PSV as the primary parameters for determining ICA stenosis. Additional parameters such as ICA/CCA PSV ratio and ICA EDV are secondary parameters and should be employed as internal checks. They are especially useful when ICA PSV may not be representative of the extent of disease. After their discussions the consensus panel recommended criteria, stratifying ICA stenosis into specific categories relevant to the CEA trials (Table 87-2). These criteria have not been subjected to widespread retrospective or prospective evaluation and do not represent the results of any one laboratory or study. They are not meant to serve as a substitute for continuous quality assurance in individual laboratories.

BILATERAL HIGH-GRADE ICA STENOSIS

Doppler-derived flow velocities from the ICA opposite an ICA occlusion or high-grade stenosis may suggest a higher degree of narrowing than is observed angiographically.² This likely is because of compensatory flow. Duplex scan overestimation of stenosis is more common in less-severe categories of stenosis than in higher-severity categories.²³

Table 87-2 Consensus Panel Recommendations for Classification of Internal Carotid Artery Stenosis²²

Normal The ICA PSV is less than 125 cm/s and there is no visible plaque or intimal thickening. Normal arteries should also have an ICA/CCA ratio of less than 2.0 and ICA EDV of less than 40 cm/s.
ICA stenosis <50% is present when the ICA PSV is less than 125 cm/s and there is visible plaque or intimal thickening. Such arteries should also have an ICA/CCA PSV ratio of less than 2.0 and an ICA EDV of less than 40 cm/s.
ICA stenosis of 50–69% is present when the ICA PSV is 125 cm/s to 230 cm/s and there is visible plaque. Such arteries should also have an ICA/CCA PSV ratio of 2.0 to 4.0 and an ICA EDV of 40 cm/s to 100 cm/s.
ICA stenosis ≥70–99% but less than near occlusion is present when the ICA PSV is more than 230 cm/s and there is visible plaque with lumen narrowing on grayscale and color Doppler imaging. The higher the PSV, the more likely (higher positive predictive value) it is to have severe disease. Such stenosis should also have an ICA/CCA ratio of more than 4.0 and an ICA EDV of more than 100 cm/s.
Near occlusion of the ICA The velocity parameters may not apply. “Preocclusive” lesions may be associated with high, low, or undetectable velocity measurements. The diagnosis of near occlusion is therefore established primarily by demonstration of a markedly narrowed lumen with color Doppler. In some near occlusive lesions, color Doppler can distinguish between near occlusion and occlusion by demonstrating a thin wisp of color traversing the lesion.
Occlusion There is no detectable patent lumen on gray-scale imaging and no flow with spectral, color, and power Doppler. Near occlusive lesions may be misdiagnosed as occlusions when only grayscale ultrasound and spectral Doppler are used.

Figure 87-8. Color flow image and velocity waveforms from a stented internal carotid artery. A peak systolic velocity of 120 cm/s indicates the stent is widely patent. The stent itself is easily recognized as a hyperechoic stripe (*arrow*) parallel to the vessel wall.

Stented Carotid Arteries

Carotid artery stenosis may be selectively treated with an intraluminal stent. However, ultrasound criteria developed for native ICAs are likely not applicable to stented carotid arteries, especially to more modest lesions in the stented arteries. With rare exceptions the number of patients in studies of stented carotid arteries that have actually had severe in-stent restenosis is small. No study has correlated the degree of stenosis or increase in ICA velocities within a stented carotid artery with clinical symptoms or outcomes. Studies have also not evaluated the effect of the stented carotid artery on the opposite nonstented artery. It is generally agreed that PSVs >125 cm/s, will be needed to identify a $>50\%$ stenosis in a stented ICA. Criteria to detect high-grade stenosis in native ICAs still work reasonably well to identify high-grade stenosis in stented ICAs (Fig. 87-8).^{24,25}

CCA and ECA Stenosis

Criteria used for classifying disease in the ICA have not been prospectively tested for application to the ECA or the CCA. However, as with the ICA, relative degrees of stenosis may be determined by the presence of plaque with B-mode imaging, aberration in color flow on duplex examination, spectral broadening, and increases in PSV. Greater than 50% stenosis can be inferred by the presence of a focally increased PSV followed by poststenotic turbulence. As noted above, the CCA waveform normally has attributes of the ICA and ECA. The CCA will take on the quality of the “normal” vessel (ICA or ECA) when the other is occluded. If there is a proximal CCA (or innominate artery) high-grade stenosis or occlusion, the ipsilateral CCA Doppler flow quality will be dampened with low PSVs and delayed upstroke of the waveform compared with the nonstenotic contralateral side. Poststenotic turbulence also may be seen. There are no widely employed validated criteria to give a diameter reduction for stenosis in the CCA or ECA. Greater than 50% stenosis in the ECA is often inferred by PSV >125 cm/s associated with poststenotic turbulence whereas a PSV >200 cm/s may be an appropriate threshold for $>50\%$ stenosis in the CCA.²⁶

LOWER EXTREMITY ARTERIAL DISEASE

The noninvasive vascular laboratory, in combination with the history and physical examination, has a critical role in providing objective diagnosis of lower extremity arterial occlusive disease in asymptomatic patients, those with intermittent claudication, and in those with critical arterial insufficiency. Both plethysmographic and ultrasound techniques are used in the evaluation of peripheral arterial disease (PAD).

In many patients the clinical history and physical examination are all that is necessary to establish a diagnosis of intermittent claudication (IC). Almost all patients with IC have diminished or absent lower extremity pulses. However, palpation of pulses is subjective and poorly reproducible. Therefore, the

pulse examination in a patient suspected of having arterial disease should be supplemented with objective testing in the noninvasive vascular laboratory. On occasion a patient will give a history suggesting IC, yet have what appear to be normal resting lower extremity pulses. In such cases, exercise testing with postexercise Doppler-measured ankle pressures and ankle–brachial systolic blood pressure ratios is crucial to confirm the diagnosis of IC secondary to arterial stenosis or occlusion (see below).

Many patients with PAD have atypical leg symptoms or are asymptomatic. Such patients have a similar increased risk of cardiovascular death as patients with typical IC symptoms, leading some to advocate for screening for PAD in patients with atypical leg symptoms or atherosclerotic risk factors.

Patients with exercise-induced lower extremity and/or buttock pain should be asked about the location of their pain, its relationship to walking, severity and duration of symptoms, and symptom progression over time. Only exercise-induced muscular pain of the calf, thigh, or buttock, relieved within a few minutes of rest and reproduced by additional walking, can be predictably improved by lower extremity arterial revascularization. There are no data on the response of atypical leg symptoms to revascularization in patients with evidence of PAD.

Ischemic pain at rest is a clinical diagnosis. It is suspected when a patient complains of pain and/or numbness in the forefoot, toes, or instep at rest. In such patients the vascular laboratory can objectively confirm and quantify the magnitude of arterial insufficiency. Ischemic pain is generally associated with an ankle pressure < 50 mm Hg and an ABI ≤ 0.4 .

PLETHYSMOGRAPHIC TECHNIQUES

Volume Flow

Calf or foot blood flow can be recorded with a mercury-in-silastic strain gauge. Electrical resistance of the mercury column depends on the length of the column. Changes in electrical resistance, reflect changes in the volume of the extremity, and are based on detection of minute changes in the length of the column. However, neither calf nor foot blood flow at rest differ between normal subjects and patients with even rather severe IC.²⁷ Hyperemic volume flow is often lower in patients with occlusive disease but such testing can be quite painful for the patient. Measurements of volume flow therefore are not very useful in the evaluation of lower extremity ischemia.

Pulse Volume Recordings (PVR)

5 Air plethysmography can be used to display pulse volume waveforms. PVRs are obtained with partially inflated blood pressure cuffs that detect volume changes sequentially down a limb. Volume changes beneath the cuffs resulting from the pulse wave result in small pressure changes within the cuffs. These changes are displayed as arterial waveforms with the use of appropriate transducers. A normal pulse volume waveform has a sharp systolic upstroke and peak, as well as a prominent dichroic notch on the downward portion of the curve. With increasing proximal arterial occlusion, the dichroic notch is lost and the waveform bows out on the down portion of the systolic portion of the curve. The peak of the pulse wave also becomes rounded and there is loss of amplitude of the wave as disease is more severe. With even more severe disease there are nearly equal upstroke and downstroke times and in very severe proximal disease the pulse wave is absent (Fig. 87-9).^{28,29} An absence of quantitative data limits the utility of PVRs. More quantitative data for the evaluation of lower extremity arterial disease are available using ultrasound-based techniques.

Figure 87-9. Pulse volume recordings. The plethysmographic waveforms are normal on the right and severely abnormal in the left leg with loss of amplitude of the waveform, slowing of the upstroke of the waveform and outward bowing of the downstroke of the waveform.

ULTRASOUND TECHNIQUES

Ankle–Brachial Index

6 The ankle–brachial index (ABI) is a very useful measure of overall lower extremity perfusion. The test is performed with the patient supine and having rested for a few minutes. A pneumatic pressure cuff is placed just above the ankle and inflated to supra systolic levels. A continuous wave Doppler probe is positioned over the posterior tibial or dorsalis pedal artery distal to the cuff. The cuff is deflated and the pressure reading when the Doppler signal returns is recorded. The sequence is repeated for the other ankle artery and the values compared with the highest brachial artery systolic pressure also obtained with the Doppler. For clinical purposes, the higher ipsilateral dorsal pedal or posterior tibial pressure is divided by the higher brachial artery systolic pressure, yielding an ABI for that lower extremity. The use of a ratio makes the test relatively independent of day-to-day variations in arterial blood pressure.

A normal ABI is 1.0 to 1.2, with progressively lower values corresponding to worsening arterial disease ([Table 87-3](#)). ABIs below normal indicate relative lower extremity arterial insufficiency and increased risk of cardiovascular death with the risk increasing with the magnitude of depression of the ABI. This test has several limitations. Significant bilateral subclavian or axillary artery occlusive disease results in a falsely elevated ABI. Calcified tibial arteries that can frequently occur with diabetes or renal failure may be inadequately compressed by the pressure cuff. This also results in a falsely elevated (supra systolic) ankle pressure. An ABI >1.4 should therefore also be considered abnormal. Such patients often have severe arterial disease and are also at increased risk of cardiovascular death. When the ABI may be falsely elevated, qualitative analysis of Doppler-derived analog or plethysmographic waveforms or measurement of digital systolic pressures is a more appropriate indicator of the arterial status of the lower extremity. Other problems with ABI include confusion with venous signals when the ankle arterial pressure is low or unmeasurable and relative insensitivity to certain patterns of progression of arterial disease. A tibial artery can occlude without a change in ABI if the remaining

tibial vessels remain patent. High-grade stenosis may also progress to occlusion without a change in ABI.

Table 87-3 Correlation between Ankle Brachial Index and Clinical Severity of Lower Extremity Arterial Ischemia

ABI	Clinical Status
>1.3	Abnormal, significant arterial wall calcification
1.1 ± 0.1	Normal
0.6 ± 0.2	Intermittent claudication
0.3 ± 0.1	Ischemic rest pain
0.1 ± 0.1	Impending tissue necrosis

Segmental Limb Pressures

Multiple pneumatic cuffs may be used along the lower extremity to determine the arterial blood pressure at specified levels. These “segmental leg pressures” are compared with the higher brachial artery systolic pressure, with other locations in the ipsilateral leg and with the corresponding levels in the contralateral extremity. Three or four cuffs may be used. In the four-cuff technique cuffs are placed: (1) as far proximal on the thigh as possible; (2) immediately above the knee; (3) just below the knee; and (4) just proximal to the ankle. Each cuff width should be 20% greater than the diameter of the limb at the point of application to avoid falsely elevated pressure readings induced by too narrow a cuff.³⁰ For the thigh, this generally necessitates a single, wide, thigh cuff. Use of two cuffs above the knee, however, can permit assessment of inflow at or proximal to the common femoral artery with the proximal cuff, and permit evaluation for the presence of superficial femoral artery disease by the distal thigh cuff. With two thigh cuffs the most proximal thigh cuff is often too narrow. An artificially elevated pressure in the proximal thigh is then expected. Therefore the high-thigh index, comparing the proximal thigh pressure to the brachial pressure, is normally about 1.4 with the four-cuff technique and 1.0 to 1.1 with the three-cuff technique (Fig. 87-10).

A hand-held Doppler is used to detect the most prominent Doppler signal at the ankle. Examination proceeds proximal to distal. First the high-thigh cuff is inflated until the ankle Doppler signal is no longer audible. The cuff is then deflated and the pressure where there is return of the Doppler signal at the ankle is the high-thigh pressure. The above-knee, below-knee, and ankle pressures are similarly determined. If there is no audible ankle Doppler signal, the popliteal artery is insonated with the Doppler to determine high-thigh and above-knee pressures. Comparison of the pressures measured at each location permits an estimation of the location of occlusive lesions (Fig. 87-11).

Figure 87-10. Segmental pressures multiple pneumatic cuffs may be used along the lower extremity to determine the arterial blood pressure at each level. Comparison of the pressures measured at each location permits an estimation of the location of occlusive lesions. Use of two cuffs above the knee can permit assessment of inflow at or proximal to the common femoral artery with the proximal cuff, and permit evaluation for the presence of superficial femoral artery disease by the distal thigh cuff. In many patients, however, the high-thigh cuff is relatively narrow compared to the diameter of the thigh resulting in an artificial elevation of the high-thigh pressure so that with use of four cuffs the high-thigh pressure will be 30 to 40 mm Hg higher than the highest brachial pressure.

There are multiple limitations in the interpretation of segmental limb pressures. The high-thigh pressure is subject to particular interpretation difficulties. A diminished high-thigh pressure can reflect an occlusive lesion anywhere at or proximal to the common femoral artery bifurcation. Low high-thigh

pressures therefore may reflect a pressure-reducing stenosis in the ipsilateral common or external iliac artery, a common femoral artery lesion or tandem pressure-reducing lesions in the profunda femoris and the proximal superficial femoral artery or any combination of such lesions. The accuracy of segmental pressures may be affected by mural calcification resulting in artificially elevated pressures. Diminished proximal pressures may also mask gradients that exist further down the leg. Segmental pressures also do not allow differentiation between short- and long-segment occlusions, or between occluded and patent, but highly stenotic arteries.

Figure 87-11. Segmental pressure examination with use of thigh, calf, and ankle cuffs. A drop in pressure of 30 mm Hg between levels indicates a hemodynamically significant stenosis between the two adjacent cuffs. This study therefore indicates a flow-reducing lesion somewhere at or proximal to the common femoral artery bifurcation on the right side and likely superficial femoral artery/popliteal artery occlusive disease on the left.

Exercise Testing

Doppler-determined pressures can be combined with treadmill exercise testing in patients without a contraindication to exercise. After determination of resting supine ankle pressures and ABIs, the patient walks on a treadmill with a predetermined incline at a predetermined rate. The test continues for 5 minutes or until the patient is forced to stop. The type, time-to-onset, and location of symptoms are recorded. At completion of the test, the patient is immediately placed supine and absolute ankle pressures and ABIs determined.

In most patients exercise testing serves only to confirm a diagnosis of claudication. It is not required in a patient with classic symptoms of claudication, absent peripheral pulses and a diminished ABI. In some cases exercise testing can document a physiologic response to revascularization or provide an objective assessment of the potential postoperative physiologic benefit.

Exercise testing is particularly useful in the infrequent patient with symptoms of claudication and who has palpable pedal pulses and/or a normal ABI. Patients with exercise-induced leg pain occurring on the basis of arterial insufficiency will show a decrease in the postexercise ankle pressures and ABI. Exercise testing can also be used to document an ischemic response to exercise in a patient with PAD and other conditions that may limit their ability to walk. Patients with COPD, arthritis, venous disease, and PAD are often more limited in their walking ability by these coexisting conditions than by their PAD. If the patients cannot complete a treadmill examination, and no ischemic pressure response to exercise occurs, it is highly unlikely their walking ability would be improved by a revascularization procedure.

The precise endpoints and techniques of exercise testing are controversial. Some laboratories exercise patients at low speeds with no inclination of the treadmill whereas others utilize various inclines and graded increases in treadmill speed. Both initial and absolute claudication distances can be determined. Initial claudication distance is the point where the patient initially experiences claudication-type pain. The absolute claudication distance is where the patient can no longer continue to walk on the treadmill.

Criteria for a positive exercise test include a decrease in the ankle pressure of 20 mm Hg or 20%, a decrease in the ABI of 0.2 in the symptomatic extremity, or failure of the ankle pressure to return to baseline within 3 minutes of completing the treadmill portion of the examination. Because systemic pressure and therefore arm pressures, depending on work load, will increase with exercise, use of the

ABI alone to indicate a positive exercise test is incorrect. The ABI decrease should be accompanied by an absolute pressure drop at the ankle.

7 Failure of the ankle pressure to drop with exercise along with failure of the ABI to decrease 20% with exercise, combined with a normal resting ABI, substantially rules out arterial insufficiency as the etiology of the patient’s exercise-induced complaints of leg pain. An exception is the rare patient with buttock claudication secondary to isolated internal iliac disease.

Neurogenic claudication may be confused with arterial ischemia. Patients present with symptoms of exercise-induced leg or calf pain. Careful questioning, however, reveals atypical characteristics for vascular-induced exercise-associated pain. Such characteristics include occurrence of pain with standing, pain relief when leaning forward, worsening with coughing, and prolonged time for pain to resolve following exercise. These patients often have normal ankle pressures at rest that do not decrease with exercise despite onset of symptoms. Failure of the ankle pressures to decrease with exercise may also be a clue to the presence of other uncommon conditions, such as venous claudication and chronic exercise-induced compartment syndromes.

Doppler Analog Waveform Analysis

Similar to plethysmographic waveforms, continuous-wave Doppler waveforms may also be analyzed qualitatively. Normal lower extremity Doppler waveforms are described as triphasic with a sharp systolic upstroke, an end-systolic reverse flow component followed by low flow forward through diastole. The shape of the waveform changes with increasing severity of proximal obstruction. Initially, the reverse-flow component is lost. As proximal stenosis increases, the rate of rise of the systolic upstroke is decreased, the amplitude of the waveform is diminished, and diastolic flow increases relative to systolic flow.

Continuous-wave Doppler waveforms are generally used in conjunction with measurement of segmental Doppler pressures similar to the use of PVRs. Doppler waveform analysis can also be used to assess iliac artery inflow to the common femoral artery. An attenuated common femoral artery waveform indicates proximal disease.

Peripheral Artery Duplex Scanning

Arterial duplex scanning provides detailed anatomic and hemodynamic information from the infrarenal aorta to the distal tibial vessels that cannot be determined by indirect testing. Arterial duplex scanning has been prospectively compared with angiography to establish standard criteria for normal and diseased arteries.³¹ Sensitivity of duplex examination for detecting the presence of a hemodynamically important lesion (>50%) ranges from 89% at the iliac artery to 68% at the popliteal artery. Overall sensitivities for predicting interruption of patency are 90% for the anterior and posterior tibial arteries and 82% for the peroneal artery. The technique is versatile and does not appear to be significantly influenced by the presence of previous operations or multilevel disease (Fig. 87-12A,B).

Velocity Patterns and Classification of Percent Stenosis

In the absence of arterial stenosis or occlusion triphasic waveforms are maintained throughout the length of the lower extremity but PSV decreases from the iliac to the tibial vessels. There are no significant differences in velocity measurements among the three tibial arteries in normal subjects.

Important changes in the velocity waveforms that signify disease include the absence of an end-systolic reverse flow component and elevation of the PSV. A 50% reduction in arterial luminal diameter (equivalent to a cross-sectional surface area reduction of 75%) is associated with a pressure drop across the lesion. The University of Washington criteria for classification of peripheral arterial stenosis are shown in Table 87-4.³²

Table 87-4 University of Washington Duplex Criteria for Determination of Stenosis in Lower Extremity Arteries

Degree of Stenosis (%)	Duplex Ultrasound Criteria
0	Normal waveform and velocities
1–19	Normal waveform and velocities with spectral broadening
20–49	Marked spectral broadening, 30% increase in PSV
50–99	Marked spectral broadening, 100% increase in PSV
Loss of reverse flow component of waveform	
Occluded	No detectable flow signal in well-visualized artery

PSV, peak systolic velocity.

Figure 87-12. A: Duplex images/waveforms and corresponding angiogram of an abrupt popliteal artery occlusion. B: Duplex waveforms and angiographic images in a patient with severe in-stent stenosis of superficial femoral artery stents.

A PSV ratio, comparing the velocity within the stenosis to the velocity just proximal to the stenosis, is also useful for grading degree of stenosis. PSV ratios are independent of changes in blood pressure, cardiac output, and vascular compliance. Grading stenosis using the PSV ratio has been found to be highly reproducible.^{33,34} Fifty percent stenosis in lower extremity arteries correlates with a PSV ratio from 1.4 to 3.0.^{31,35–38} A velocity ratio of 2.0 is a reasonable compromise and is used by many vascular laboratories as indicative of a 50% peripheral arterial stenosis.

Lower extremity duplex scanning can serve as an alternative to contrast arteriography in the preoperative assessment of candidates for arterial intervention. In selected centers, successful lower extremity revascularization either by open arterial bypass grafting or with catheter-based techniques has been reported using only arterial duplex in a high percentage of cases.^{39–41} The limiting factor with preoperative arterial duplex is the ability to accurately identify the best site for the distal anastomosis of a bypass graft, especially when the distal anastomotic site is below the knee.⁴²

The role of duplex ultrasound scanning in the surveillance of lower extremity vein grafts has been well documented (Fig. 87-13A,B). Detection and repair of a graft-threatening stenosis detected by duplex scanning appears to improve secondary graft patency.^{43–46} Twenty to thirty percent of vein grafts will develop a severe enough stenosis that revision is recommended.⁴⁷ Approximately 80% of these graft stenotic lesions develop in the first postoperative year. However, graft threatening lesions can develop at any time. Surveillance is therefore generally recommended for the life of the graft. A widely utilized protocol for vein graft duplex surveillance is every 3 months for the first year and every 6 months to yearly thereafter. The examination involves point-to-point insonation of the proximal inflow artery, proximal anastomosis, midgraft, distal anastomosis, and the distal outflow artery. A PSV ratio of 4, or a PSV above 300 cm/s, indicates a critical graft stenosis, and repair of the lesion by open or catheter-based techniques should be considered.⁴⁸ If the PSV ratio is between 2 and 4, the patient should be evaluated again in 3 months with a duplex examination.

Aneurysms and pseudoaneurysms of lower extremity arteries are also readily identified and characterized with duplex scanning with particular attention to the diameter of the aneurysm and the

presence or absence of intraluminal thrombosis (Fig. 87-14A,B).

Figure 87-13. A and B: Duplex ultrasound images and velocity waveforms of normal (A) and stenotic (B) proximal anastomoses of femoral tibial bypass grafts. The abnormal study has a severe elevation in flow velocity of 558 cm/s indicating a high-grade stenosis.

Figure 87-14. A: Native popliteal artery aneurysm with intraluminal thrombus. **B:** Large pseudo aneurysm of the right common femoral artery resulting from arterial infection from intra-arterial injection of street drugs.

Upper Extremity Arterial Evaluation

Upper extremity arterial disease is a small but important component of vascular surgical practice. Both ultrasound and plethysmographic techniques are important in the evaluation of upper extremity arterial disease.

SEGMENTAL ARM PRESSURES

Upper extremity segmental pressures are obtained by measuring blood pressure with pneumatic cuffs above the elbow, below the elbow, and above the wrist while insonating the radial or ulnar artery at the wrist using a continuous wave Doppler. Doppler-derived or plethysmographic waveforms can also be recorded at the different levels. Abnormal waveforms or pressures will help diagnose arterial disease proximal to the wrist.

A 12-cm blood pressure cuff is usually sufficient for measuring the brachial artery pressure, whereas a 10-cm blood pressure cuff is used at the wrist to measure the systolic pressure from the radial and ulnar arteries. A systolic pressure measurement is taken from the upper arm (brachial artery) and at the wrist (radial and ulnar arteries). Normally, there is not a recordable gradient between any of these sites and a normal wrist/brachial blood pressure ratio is 1.0. If there is a blood pressure difference between the two arms of more than 15 mm Hg, it is likely that there is a stenosis or occlusion somewhere on the side of the lower pressure. Abnormal waveforms and decreased pressures at the above-elbow cuff site indicate axillary, subclavian, or brachiocephalic arterial occlusive disease. Similarly, abnormalities at the below-elbow and above-wrist sites indicate brachial and proximal ulnar/radial arterial occlusive

disease, respectively. If there is a blood pressure difference between levels, or between the radial and ulnar arteries, of more than 15 mm Hg it is likely caused by a stenosis or occlusion (Fig. 87-15).

DIGITAL PRESSURES AND PLETHYSMOGRAPHY

Digital pressure measurements and digital plethysmography are extremely useful in the diagnosis of upper extremity arterial disease and can be as accurate as arteriography in assessing patients with hand ischemia.⁴⁹ Photo plethysmography (PPG) or strain-gauge plethysmography can be used to measure digital blood pressure and to obtain pulse waveforms. PPG is preferred because the equipment is easier to use and more durable. An additional advantage of PPG is that it is possible to record the volume pulses from the tips of the digits. This may also be useful in documenting obstruction within the digit arteries themselves.

The photo cell is attached to the fingertip pulp with double-sided tape or small strain gauges are placed around the fingertip. One-inch (2.5 cm) blood pressure cuffs are placed around the proximal phalanx. Waveforms are recorded using pulse tracings obtained at high speed to evaluate the shape of the waveform. Waveforms are normal if the upstroke time is less than 0.2 seconds (Fig. 87-16A). They may or may not have a dichotic notch. An abnormal obstructive waveform will have a rounded peak, as opposed to the normal notched peak. Upstroke time is prolonged. The amplitude of the waveform is not important. Finger PPG waveforms are not quantitative. The amplitude of the waveform is primarily dependent on the gain setting, not blood flow.

Patients with vasospasm will often have an abnormally shaped waveform termed a “peaked pulse,” which is thought to represent abnormal elasticity and rebound of the palmar and digital vessels (Fig. 87-16B).

Finger blood pressures are measured by inflating the cuffs placed at the base of the fingers. At reduced chart recorder speed the pulsations are recorded while the blood pressure cuffs are inflated. When digit pulsations are obliterated, the cuff is slowly deflated until the pulsation returns. The pressure reading at this point is recorded and represents the digital artery pressure.

It is extremely important to measure and record finger temperature before performing digital plethysmography and obtaining finger blood pressures. If the finger temperature is less than 28 to 30°C false-positive results may be obtained secondary to cold-induced vasospasm. It is recommended that hand and/or whole-body warming be performed in patients with low finger temperatures.

Digital blood pressure is normally within 20 to 30 mm Hg of brachial pressure. A ratio of finger systolic pressure to brachial systolic pressure of greater than 0.80 is normal but does not necessarily rule out digital artery occlusive disease. It is important to remember that there are occasional patients with very distal digital artery occlusive disease with normal finger pressures since the digital cuff is around the proximal phalanx. Also, occlusive disease in a single digital artery can be missed if the other digital artery in that finger is normally patent.

Figure 87-15. Upper extremity segmental pressures and Doppler waveforms. The findings are normal on the right and suggest radial and ulnar artery or distal brachial artery occlusive disease on the left.

COLD CHALLENGE TESTING

The simplest cold intolerance test is to measure the digital temperature recovery time after immersion of the hand in ice water for a short time period. Preimmersion digital temperatures must be above 30°C. Hand and body warming may be required prior to immersion.

Using a thermistor probe to measure finger temperatures, the patient's hand is immersed in a container of ice water for 30 to 60 seconds. After the hand is dried, the fingertip pulp temperatures are measured every 5 minutes for 45 minutes, or until the temperature returns to preimmersion levels. Normal individuals will have a recovery time to preimmersion levels of less than 10 minutes. This test is very sensitive for detecting cold-induced vasospasm but is nonspecific, with approximately one-half of patients with a positive test having no clinical symptoms of cold sensitivity.⁵⁰ Cold immersion testing is also uncomfortable and poorly tolerated by patients with significant Raynaud syndrome symptoms. Pressures often fall to unrecordable levels in such patients.

A better, but infrequently utilized, test for cold sensitivity is the digital hypothermic challenge test as described by Nielsen and Lassen (Fig. 87-17).⁵¹ This test involves placing a finger cuff around the proximal phalanx on the test finger and perfusing the cuff with progressively cooler fluid. The pressure in the test finger is then compared with that in a reference finger that is not cooled. The Nielsen test is interpreted as positive for abnormal cold-induced vasospasm if the test finger pressure is reduced by more than 17% compared with the reference finger.

Other tests for cold-induced vasospasm include thermal entrainment, digital laser Doppler response to cold, thermography, venous occlusion plethysmography, and digital artery caliber measurement. None are widely accepted or employed.⁵²⁻⁵⁴

Figure 87-16. A and B: Normal (A) and “peaked pulse” (B) digital photoplethysmographic (PPG) waveforms. A normal waveform has a rapid upstroke and a sharp apex whereas an obstructive waveform would demonstrate a delayed upstroke and rounded apex. In a peaked pulse, waveform suggestive of vasospasm, the dichroitic notch slides to high on the systolic downslope of the waveform.

Figure 87-17. Device for performance of digital hypothermic challenge or Nielsen test. The cuff on the second finger is used to cool the test finger and measure digital pressure. This allows controlled application of cold to induce a vasospastic response. The fourth finger is the reference finger. Strain gauges on the finger tips are used to measure the digital pressures. See text.

UPPER EXTREMITY DUPLEX SCANNING

Duplex scanning of the upper extremity is carried out in a manner similar to arterial examination elsewhere. The origins of the brachial cephalic vessels can be difficult to visualize with duplex scanning. For examination of the origin of the subclavian artery a 3- or 5-MHz transducer with a small footprint probe using the sternal notch as a window generally gives the best images. One study found 48 of 50 right subclavian artery origins (96%) and 25 (50%) of 50 left subclavian artery origins could be visualized by color duplex scanning.⁵⁵

Criteria for stenosis at the origins of brachial cephalic arteries are slightly different than those used elsewhere. A PSV ratio of ≥ 2 indicates stenosis at the origin of a brachial cephalic artery. Stenosis can also be implied by monophasic flow without actual visualization of a high-velocity jet and by reverse flow in a vertebral artery. Such additional criteria are necessary to assess the origins of the brachiocephalic vessels. If only PSV ratios are utilized there would be higher numbers of both false-positive and false-negative results.⁵⁵

More distally the upper extremity arteries are relatively superficial and fairly constant in location. They are best scanned with a higher-frequency probe such as a 7.5- or 10-MHz probe. Either a sector or linear scan head may be used, but in either case a standoff or mound of acoustical gel is helpful to visualize the vessel clearly and to assess the flow pattern within it. Color facilitates identification of the vessels, and tortuosity of the upper extremity arteries may be more easily seen with color flow imaging.

Stenosis, occlusions, and aneurysms of upper extremity arteries are all readily identified with ultrasound (Fig. 87-18A–C).

The interpretation of duplex findings in the upper extremity beyond the origins of the vessels is similar to the interpretation of B-mode images and Doppler signals gathered in other arterial systems.⁵⁶ Normal waveforms in the upper extremity arteries are usually triphasic. As elsewhere in the arterial system, stenosis will produce high-velocity jets, poststenotic turbulence, and dampened distal waveforms. There are, however, at present no specific frequency or velocity criteria with which to gauge the severity of stenosis in the upper extremity arteries. Some general guidelines are listed in Table 87-5. The diagnosis of arterial occlusion is made by imaging the artery and using the pulsed Doppler to show that there is no flow within the lumen.

Figure 87-18. A: Duplex color flow image and velocity waveform with corresponding angiogram in a patient with brachial artery stenosis (*arrow*) and symptomatic arm ischemia secondary to a crutch injury. Note the loss of the end-systolic reverse flow component of the arterial waveform. B: Duplex image of a right axillary artery occlusion secondary to embolism. Note the occlusive waveform and reconstitution of the artery via a distal branch vessel (*arrow*). C: Grayscale image of a small subclavian artery aneurysm.

Table 87-5 Duplex Ultrasound Criteria for Evaluation of Upper Extremity Arterial Stenosis

Condition	Characteristics
Normal	Uniform waveforms; biphasic or triphasic waveforms; clear window beneath systolic peak
<50% diameter reduction	Focal velocity increase; spectral broadening; possibly triphasic or biphasic flow
>50% diameter reduction	Focal velocity increase; loss of triphasic or biphasic velocity waveform; poststenotic flow (color bruit)
Occlusion	No flow detected

For patients with unilateral symptoms who may have a surgically correctable lesion such as a subclavian artery aneurysm or stenosis, duplex scanning is quite useful.⁵⁷ The duplex evaluation of

aneurysms is based upon the B-mode image appearance, with the most important feature being the size of the enlarged artery and the presence of intraluminal thrombus that may serve as a source of distal embolization. Presence or absence of flow within the aneurysm can be determined by the Doppler component.

Duplex scanning may be of use in patients with suspected embolization to identify proximal aneurysms, but the evaluation should also include echocardiography to look for mural thrombi and valvular lesions. While duplex scanning alone cannot be used to make the diagnosis of Takayasu arteritis, it can be a helpful adjunct in following the progression or regression of arterial involvement in response to treatment.⁵⁸

VISCERAL ARTERIES

Mesenteric Arteries

Duplex ultrasonography can serve as a valuable noninvasive screening test for splanchnic artery stenosis in patients with possible chronic mesenteric ischemia and for follow-up of mesenteric artery reconstructions. Aneurysms and dissections of the visceral arteries can also be identified (Fig. 87-19). Despite the accuracy of duplex detection of mesenteric artery stenosis, angiographic confirmation of high-grade stenosis or occlusion of the splanchnic vessels, and appropriate history and physical examination are still required for the diagnosis of chronic mesenteric ischemia. The examination is technically difficult and is best performed by vascular technologists with extensive experience in intraabdominal ultrasound techniques.

Interpretation of Mesenteric Duplex Ultrasound Studies

In healthy individuals, fasting arterial waveforms differ in the SMA versus the CA. The arterial waveforms reflect end-organ vascular resistance. The liver and spleen have relatively high constant metabolic requirements and are therefore low-resistance organs. As a result, CA waveforms are generally biphasic, with a peak systolic component, no reversal of end-systolic flow, and a relatively high end-diastolic velocity (EDV). The normal fasting SMA velocity waveform is triphasic, reflecting the high vascular resistance of the intestinal tract at rest. There is a peak systolic component, often an end-systolic reverse flow component, and a minimal diastolic flow component (Fig. 87-20A).⁵⁹

Figure 87-19. Grayscale image of a 2.15-cm hepatic artery aneurysm.

Changes in Doppler-derived arterial waveforms in response to feeding are also different in the CA and SMA. Because the liver and spleen have basically fixed metabolic demands, there is no significant change in CA velocity waveform after eating. Blood flow in the SMA, however, increases markedly after a meal, reflecting a marked decrease in intestinal arterial resistance. The postprandial waveform changes in the SMA include a near doubling of systolic velocity, tripling of the EDV, and loss of end-systolic reversal of blood flow (Fig. 87-20B).⁶⁰

Postprandial changes are maximal at 45 minutes after ingestion of a test meal and depend on the composition of the meal ingested. Mixed nutrient composition meals produce the greatest flow increase

in the SMA when compared with equal caloric meals composed solely of fat, glucose, or protein.⁶¹

Detection of Mesenteric Arterial Stenosis

8 Duplex ultrasound can detect hemodynamically significant stenosis in splanchnic vessels. In a blinded prospective study of 100 patients who underwent mesenteric artery duplex scanning and lateral aortography, a PSV in the SMA of 275 cm/s or more indicated a $\geq 70\%$ SMA stenosis with a sensitivity of 92%, a specificity of 96%, a positive predictive value of 80%, a negative predictive value of 99%, and an accuracy of 96% (Fig. 87-21). In the same study, a PSV of ≥ 200 cm/s identified a $\geq 70\%$ angiographic celiac artery stenosis with a sensitivity of 87%, a specificity of 80%, a positive predictive value of 63%, a negative predictive value of 94%, and an accuracy of 82%.⁶²

Other duplex criteria for mesenteric artery stenosis are also in use. An SMA EDV greater than 45 cm/s correlates with a $\geq 50\%$ SMA stenosis with a specificity of 92% and a sensitivity of 100%, whereas a CA EDV of 55 cm/s or greater predicts a $\geq 50\%$ CA stenosis with a sensitivity of 93%, specificity of 100%, and accuracy of 95%.⁶³

Surgical revascularization of the mesenteric arteries is a standard treatment for chronic mesenteric ischemia. Most often bypass grafts are constructed to the superior mesenteric and/or celiac arteries. Mesenteric artery bypass grafts can be followed postoperatively with mesenteric artery duplex scanning. Flow velocities within mesenteric artery bypass grafts vary little with the origin of the graft (supraceliac or infrarenal aorta or a common iliac artery) and remain stable over time. Serially increasing velocities over time in a mesenteric bypass likely suggest the development of a graft or anastomotic stenosis.⁶⁴

Figure 87-20. A: A normal fasting superior mesenteric artery (SMA) waveform may exhibit reverse flow at the end of systole and relatively low end-diastolic velocity reflecting relatively high resistance of the intestinal circulation in the fasting state. B: Postprandial SMA waveform. There has been, in comparison to A, loss of end-systolic reverse flow and an increase in end-diastolic flow as resistance in the intestinal arterial circulation falls following feeding.

Placement of an intraluminal stent is a viable alternative in many cases to surgical bypass, for the treatment of mesenteric artery stenosis. Similar to the carotid artery (see above), there is reason to suspect duplex criteria developed for stenosis in native mesenteric arteries may not be applicable without modification to stented superior mesenteric arteries. Mesenteric duplex scans pre- and postplacement of a superior mesenteric artery (SMA) stent have been compared and correlated with pressure gradients measured at the time of angiography. The data indicate that SMA stenting provides good anatomic results and significantly reduces angiographically measured pressure gradients. Duplex measured SMA PSVs are reduced poststent placement but, despite good angiographic results, remain in most cases above criteria predicting high-grade native artery SMA stenosis.⁶⁵

Figure 87-21. Color flow image and duplex-derived SMA waveform in a patient with possible chronic mesenteric ischemia. A peak systolic velocity of >330 cm/s indicates a high-grade SMA stenosis and is compatible with a clinical picture of chronic mesenteric ischemia.

RENAL ARTERIES

Duplex scanning of the renal arteries is useful in evaluating for renal artery stenosis in patients with possible renal vascular hypertension and can also be used to detect renal artery aneurysms (Fig. 87-22), as well as provide a measure of the health of the renal parenchyma.

Indirect Assessment of Renal Artery Stenosis

Indirect methods to assess renal artery stenosis evaluate interlobar arteries. Decreased acceleration times and/or presence of tardus/parvus waveforms (waveforms with delayed or slowed upstrokes) may suggest the presence of a main renal artery stenosis. These techniques are quicker and easier to perform than direct examination of the main renal artery but have been not widely validated. Improved visualization of main renal arteries with modern duplex scanners has made indirect methods of assessing the main renal artery essentially obsolete. These techniques are even less accurate in patients with bilateral stenosis and are not applicable in patients with a single patent renal artery.

Figure 87-22. Grayscale image of a large renal artery aneurysm in the hilum of the kidney.

Figure 87-23. Renal artery waveform in a patient with severe hypertension. The high peak systolic velocity is compatible with a high-grade renal artery stenosis.

Direct Assessment of Renal Artery Stenosis

Normal renal arteries have a PSV less than 180 cm/s and low-resistance waveforms reflecting the high metabolic demands of the kidney. A ratio of the PSV in the renal artery to that in the aorta (renal–aortic ratio, RAR) of ≥ 3.5 indicates a $\geq 60\%$ diameter-reducing renal artery stenosis (84% to 88% sensitivity, 97% to 99% specificity, 94% to 98% positive predictive value) (Fig. 87-23).⁶⁶ A PSV of ≥ 200 cm/s has also been suggested to indicate a $\geq 60\%$ renal artery stenosis whereas a velocity in the renal artery of >185 cm/s has been suggested to indicate a less than 60% renal artery stenosis. Therefore a renal artery can be considered normal when PSV is <180 cm/s and the RAR is <3.5 . With a PSV >180 cm/s and a RAR <3.5 , the renal artery can be considered to have a $<60\%$ stenosis. RARs of >3.5 indicate $>60\%$ renal artery stenosis regardless if the renal artery PSV is less than or more than 180 cm/s.⁶⁷ When the EDV exceeds 150 cm/s, data suggest a $>80\%$ renal artery stenosis.⁶⁸ The same criteria have been used to evaluate the patency of renal arterial reconstructions, but similar to stented carotid and mesenteric arteries may need modification for stented renal arteries.⁶⁹

Predicting Success of Renal Artery Interventions

EDVs tend to be lower in patients with renal insufficiency, indicating decreased diastolic flow and suggesting increased parenchymal resistance to blood flow. Decreased parenchymal diastolic velocities may therefore suggest renal parenchymal disease (Fig. 87-24). Many patients, 20% to 40%, treated with renal artery angioplasty and stenting or open surgical reconstructions do not have postprocedure blood pressure or renal function improvement. An estimate of resistance to flow within the renal parenchyma can be made by comparisons of EDV and PSVs of renal artery waveforms obtained from renal parenchymal arteries. The so-called resistive index (RI) is calculated as follows:

$$RI = [1 - (EDV/PSV)] \times 100$$

In effect a high RI, >0.7 is bad, suggesting renal parenchymal disease whereas a low RI is good, indicating healthy renal parenchymal tissues. Evaluation of parenchymal resistance has been suggested as a possible preprocedure predictor of clinical success of renal artery interventions.⁷⁰ Abnormal parenchymal resistance may also be a marker of renal allograft dysfunction or rejection (Fig. 87-25).

Figure 87-24. The absence of end-diastolic flow in the left renal artery indicates severe parenchymal disease of the left kidney.

VENOUS DISEASE

Acute Deep Venous Thrombosis

Physical examination is not sensitive or specific for the detection of acute deep venous thrombosis (DVT).⁷¹ Prior to the acceptance and widespread use of venous duplex scanning, impedance plethysmography (IPG) was employed as the initial noninvasive test for patients with suspected acute lower extremity DVT. IPG is a reasonably sensitive (87%) and specific (up to 100%) test for proximal (above knee) lower extremity DVT in symptomatic patients.⁷²⁻⁷⁴ However, lower sensitivities for proximal DVT (65%) have been reported in studies that exclude clinical outcomes and only report in comparison to venography. IPG may not detect nonocclusive proximal DVT, occlusive proximal DVT present in parallel venous systems, such as duplicated femoral or popliteal veins, and cannot detect DVT isolated to the calf veins.^{75,76} While IPG is still sometimes used for clinical situations felt to require serial evaluations of the proximal veins, the limitations noted above make it a substandard examination for routine clinical assessment of lower extremity DVT.⁷⁷ Currently, color flow duplex scanning performed by skilled operators provides the most practical and cost-effective method for assessment of DVT of the lower and upper extremity veins as well as for detection of thrombosis in superficial veins.

Figure 87-25. There is very little diastolic flow in the renal artery of the transplanted kidney consistent with rejection or primary allograft dysfunction.

Figure 87-26. Venous flow is typically depicted below the baseline. Venous flow in the proximal lower extremity veins should be spontaneous, vary with respiration, and augment with distal compression.

At a minimum, vascular laboratory duplex ultrasound evaluation for lower extremity DVT should include examination of the common femoral, profunda femoris, femoral, and popliteal veins. Venous waveforms from the right and left common femoral veins should always be compared. A normal lower extremity examination will show patency of the veins on color flow imaging, collapsing of the veins with application of pressure by the ultrasound probe and venous flow patterns in the common femoral and femoral veins that decrease with inspiration and increase with expiration. Flow within a patent vein should also increase with application of compression distal to the site of examination (Fig. 87-26).

9 The primary ultrasound diagnostic criteria for diagnosis of venous thrombosis is failure of the vein to collapse with application of pressure with the ultrasound probe (Fig. 87-27A,B). A continuous flow pattern in one common femoral vein and not the other suggests ipsilateral iliac vein thrombosis or external compression of the ipsilateral iliac vein. Bilateral pulsatile common femoral waveforms suggest volume overload, tricuspid regurgitation, or heart failure.

Not all venous ultrasound examinations for DVT are the same. Some vascular laboratories do not include evaluation of the calf veins as part of their routine evaluation for lower extremity DVT, even in symptomatic patients. This results from outdated perceptions of inaccuracy of calf vein ultrasound evaluation for DVT. Failure to perform a complete initial examination necessitates serial ultrasound examinations or alternative strategies to detect possible extension of venous thrombi initially isolated to the calf veins. Such strategies are inefficient, ineffective for noncompliant patients, and not cost effective compared to a single stand-alone color flow duplex study of the proximal and calf veins in patients with suspected lower extremity DVT.

Figure 87-27. A: Without compression with the ultrasound probe the femoral vein is easily visible (*white arrow*). B: With compression the vein collapses and is no longer visible (*black arrow*). Failure of the vein to collapse with probe pressure would indicate the presence of thrombus within the vein.

Limited ultrasound studies for acute DVT may include compression ultrasound (B-mode imaging only), duplex ultrasound (B-mode imaging and Doppler waveform analysis), and color Doppler alone. The sensitivities and specificities for detecting acute DVT differ among the examinations, and different examinations are appropriate for different veins. Compression ultrasound is typically performed for evaluation of proximal deep veins, specifically the common femoral, femoral, and popliteal veins. A combination of duplex ultrasound and color Doppler is more often used for calf and iliac veins. Color flow alone may be used to assess patency of the calf veins as they are difficult to reliably compress in subjects with larger legs.

Many factors will influence which venous segments can be evaluated in an individual examination. These include the presence of morbid obesity, lower extremity edema or tenderness, or the presence of immobilization devices and bandages. Overall, a complete color and Doppler examination has become the standard of care for assessment of lower extremity DVT. It is recommended that whenever possible, a venous duplex examination to exclude the presence of DVT consist of an evaluation of both the proximal and calf veins.

A well-trained technologist can interrogate calf veins in 80% to 98% of cases using a combination of B-mode, Doppler waveform analysis, and color Doppler.^{78,79} Overall accuracy of venous ultrasonography in comparison to venography has been well established. The weighted mean sensitivity and specificity of venous ultrasonography (including all types) for the diagnosis of symptomatic proximal DVT are 97% and 94%, respectively.⁷⁷ As suggested above, in technically adequate studies, the sensitivity and specificity of color Doppler to identify isolated calf vein thrombosis exceeds 90%.⁷⁹ The high specificity of venous ultrasonography allows treatment for DVT to be initiated without further confirmatory tests, and the high sensitivity in diagnosing proximal DVT makes it possible to withhold treatment if the examination is negative.

Some ultrasound examinations are limited by practical constraints. Inability of the patient to fully cooperate with regard to positioning for the examination and/or intolerance of the pressure of the ultrasound scan head on the skin, or inability of the examiner to obtain a complete examination secondary to bandages, casts, or extremity wounds, may lead to a requirement for serial examinations. An alternative diagnostic procedure, such as catheter-based contrast, MR, or CT venography may be indicated when a complete ultrasound examination is not possible or if the patient cannot or is unlikely to return for a follow-up examination. Currently, repeat or serial venous ultrasound examinations are advisable in follow-up for a limited negative examination in symptomatic patients highly suspicious for DVT in whom an alternative form of imaging is unavailable or contraindicated.

The diagnosis of pulmonary embolism (PE), like that for DVT, also cannot be established without

objective testing. Several studies have evaluated lower extremity venous ultrasound examinations in patients suspected of PE. These studies, often employing ultrasound of only the proximal veins and nuclear medicine-based ventilation perfusion (V/Q) scanning, unfortunately have little relevance to modern practice where complete proximal and distal vein ultrasound examinations are usually routine, and where CT pulmonary angiography (CTPA) or MR pulmonary angiography (MRPA) have largely supplanted V/Q scanning.

The rationale for venous ultrasonography in patients who present with symptoms of PE is that a diagnosis of DVT may indirectly suggest a diagnosis of PE, making additional investigation to exclude PE unnecessary in some clinical settings. However, ultrasound cannot make a definitive diagnosis of PE. Patients can have DVT and pulmonary symptoms or hemodynamic instability from causes other than PE.

Normal bilateral proximal venous ultrasound scans do not rule out PE. When PE is definitively present, DVT of the proximal lower extremity veins is detectable by compression ultrasound in only 50% of patients.⁸⁰ When a PE is objectively diagnosed with no evidence of lower extremity DVT, the PE may have originated from pelvic veins, arm veins, or possibly embolized completely from a lower extremity vein. An objective diagnostic test for PE is therefore indicated in most cases. Currently, in most centers this would be a CT pulmonary angiogram.

Chronic Venous Insufficiency (CVI)

The presence of venous insufficiency can also be evaluated with either air or photoplethysmography and with duplex scanning.⁸¹ In theory, air plethysmography (APG) can provide an analysis of overall venous hemodynamics including evaluation of the individual components of venous function; reflux and the efficacy of the calf muscle pump. A flexible chamber is placed on the calf and volume changes then induced by a series of positional and exercise maneuvers. Measurements derived from these maneuvers are then used to calculate measures of venous reflux (venous filling index [VFI]), calf muscle pump function (ejection fraction [EF]) as well as a measure of overall venous function termed the residual volume fraction. Of these values VFI has the potential for being the most important. A VFI of >2 mL/s indicates abnormal reflux with values >10 mL/s indicating increased risk of cutaneous changes associated with chronic venous insufficiency. APG, however, while theoretically interesting, is used only infrequently in clinical practice.

Photoplethysmography (PPG) is a variant of plethysmography techniques to assess venous reflux. It detects changes in the blood content of the skin that theoretically reflect venous volume. It consists of a light emitting diode and a photo sensor. The diode transmits light into subcutaneous tissues. Blood attenuates light in proportion to its content in tissue. The PPG machine amplifies the difference between the transmitted and reflected signal and converts it into a waveform. To assess for venous reflux the sensor is typically applied to the medial ankle area (Fig. 87-28). The patient performs a series of plantar and dorsal flexion maneuvers of the foot decreasing the venous volume of the extremity. The time for the waveform to return to baseline is termed the venous recovery time (VRT). A normal PPG VRT is 20 seconds or greater. Shorter times indicate the presence of venous reflux. If the VRT returns to normal with the application of a superficial venous tourniquet then the reflux is confined to the superficial venous system (Fig. 87-29). If the VRT does not correct with a superficial venous tourniquet deep venous reflux is present. Neither, APG or PPG can provide information about the specific venous segments that are abnormal. That information can be provided by duplex ultrasound.

Figure 87-28. Placement of PPG probes for assessment of venous reflux.

Figure 87-29. Venous PPG waveforms in a patient with superficial venous reflux. The patient is asked to perform 10 dorsal and plantar flexions of the ankle resulting in emptying the leg of venous blood. In the top panel the veins refill very rapidly indicating the presence of venous reflux. Refill slows with application of a tourniquet to occlude the superficial veins indicating this patient likely has only reflux in the superficial venous system and no deep venous reflux.

10 Duplex ultrasound can provide important physiologic and anatomic information in patients with possible CVI. Both sites of reflux and of venous obstruction can be determined in deep, superficial, and perforating veins. In patients with valve incompetence, reflux can be stimulated and then detected with duplex using a Valsalva maneuver, manual compression proximal to the transducer, or release of compression distal to the transducer. The examination has been standardized with the patient upright and using deflation of a series of pneumatic cuffs at specific sites on the leg with the leg under examination not bearing weight. In the upright position, reflux stimulated by cuff deflation that lasts more than 0.5 second is indicative of pathologic reflux.⁸² The technique allows localization of reflux to specific venous segments and can serve as a valuable preoperative planning tool to target specific venous segments for removal or reconstruction (Fig. 87-30). It has a sensitivity of 82% and specificity of 100% for the identification of competent and incompetent perforating veins. Duplex determination of reflux sites and sites of venous occlusion as a means of assessing overall venous hemodynamics is not established. Currently duplex assessment of venous reflux provides the basis of planning for the large majority of venous procedures designed to treat the manifestations of superficial venous reflux.

Figure 87-30. Popliteal venous waveform with cuff deflation for duplex assessment and localization of venous reflux. Reflux lasting >0.5 to 1 second is abnormal.

SELECTED MISCELLANEOUS EXAMINATIONS

Evaluation for Abdominal Aortic Aneurysm

Vascular laboratory ultrasound screening for abdominal aortic aneurysm (AAA) in males >65 years with a history of cigarette smoking has been shown to be effective in preventing aneurysm related deaths in this cohort.⁸³ Ultrasound is highly accurate and reproducible in measuring the diameter of infrarenal AAAs (Fig. 87-31). Typically patients with AAA diameters below accepted threshold levels for repair are followed with serial ultrasound examinations to monitor for enlargement of the aneurysm to a diameter where repair is indicated.

Figure 87-31. Ultrasound image of a 5.9-cm infrarenal abdominal aortic aneurysm with acentric intraluminal thrombus.

Figure 87-32. Ultrasound examination of an aortic stent graft. The aortic stent graft (*arrows*) is visible within the lumen of the residual aneurysm sac measuring 8.36 cm × 7.99 cm.

Evaluation of Aortic Endografts

Placement of endoluminal stent grafts is now standard therapy for most patients with AAA. With stent grafting of an AAA the aneurysm is left in situ and blood flow diverted through the stent graft. Some stent grafts eventually leak at proximal or distal attachment sites. AAAs with these so-called type I endoleaks are at increased risk of rupture. In addition, AAAs treated with stent grafts may also occasionally enlarge because of back pressure in the aneurysm sac from patent lumbar vessels; type II endoleak. Patients whose AAAs enlarge in association with type II endoleaks after endografting are also considered at risk for aneurysm rupture.

Standard monitoring of endoluminal stent grafts is with serial CT scans to detect endoleak and changing aneurysm sac diameter. However, there are increasing concerns about repeated doses of contrast and radiation exposure associated with serial CT scans. It now appears many stent grafts can be followed with serial duplex ultrasound examinations. Duplex ultrasound is capable of measuring sac diameter (Fig. 87-32) and detecting both type I and II endoleaks. Even if an endoleak cannot be detected by ultrasound an increase in sac diameter following stent grafting should prompt further investigation. In some centers duplex ultrasound has replaced CT scanning as the preferred method of follow-up of AAA stent grafts.^{84,85}

Evaluation and Treatment of Groin Pseudoaneurysms

Pseudoaneurysms can occur as a complication of an arterial puncture in the groin performed for diagnostic or therapeutic angiography. Groin pseudoaneurysms are readily detected with duplex ultrasound (Fig. 87-33). Color flow demonstrates a typical collection of flowing blood usually anterior to the artery from which the pseudoaneurysm originates. The native artery and the pseudoaneurysm are connected by a so-called “neck.” To-and-fro flow within the neck of the pseudoaneurysm is characteristic and pathognomonic of a pseudoaneurysm arising from an arterial puncture.

Treatment of pseudoaneurysms may be with direct surgical repair or, utilizing the vascular laboratory, direct compression of the pseudoaneurysm until it clots using the ultrasound scan head to both locate the pseudoaneurysm and apply pressure. Alternatively, the pseudoaneurysm is visualized with the ultrasound scan head and a needle introduced into the body of the pseudoaneurysm for injection of small amounts of thrombin to induce thrombosis of the pseudoaneurysm.⁸⁶ All techniques are effective but currently direct thrombin injection is favored in most cases as it is relatively noninvasive and less painful and more effective than prolonged compression alone.^{87,88}

Figure 87-33. A pseudoaneurysm of the superficial femoral artery following arterial cannulation. The so-called neck of the aneurysm (*arrow*) is readily visible.

Transcutaneous Oxygen (TCpO₂) Measurements

Measurements of transcutaneous oxygen can be performed as an aid in predicting healing of pedal lesions or healing of an amputation at the site where the measurement is taken (Fig. 87-34). In general, a TCpO₂ >30 mm Hg indicates healing is likely, measurements between 20 and 30 mm Hg are equivocal for healing and measurements below 20 mm Hg indicate healing is unlikely.⁸⁹ Measurements are not influenced by the presence of diabetes but it has been suggested the level for predicting healing be increased to 40 mm Hg in patients with diabetes. The test is less accurate in the presence of edema, cellulitis, hyperkeratosis, and in older patients.

Figure 87-34. A transcutaneous oxygen probe. TCpO₂ measurements can serve as an aid in determining healing potential of pedal wounds or ulcers.

Chapter 88

Vascular Infection

Jayer Chung and J. Gregory Modrall

Key Points

- 1 The pathogenesis of infected aneurysms involves seeding of a pre-existing aneurysm by bacteremia.
 - 2 The pathogenesis of microbial arteritis involves hematogenous seeding of an atherosclerotic plaque.
 - 3 The pathogenesis of infected aortitis involves direct spread of infection to the aorta by contiguous septic structures, such as vertebral osteomyelitis.
 - 4 The pathogenesis of arterial graft infections involves seeding of the graft from intraoperative contamination, erosion of adjacent structures, or hematogenous seeding from a distant source.
 - 5 Characteristics of a prosthetic graft that predispose to graft infection include lowering of the bacterial bioburden required to cause a graft infection, surface irregularity that permits bacterial attachment, abrogation of local defense against infection, and creation of the bacterial biofilm that protects microbes from host defenses and antibiotics.
 - 6 The most common organisms causing arterial graft infections are skin flora, especially *Staphylococcus aureus* and *Staphylococcus epidermidis*.
 - 7 Of the available surgical options for aortic graft infections, treatment with graft excision, aortic ligation, and extraanatomic bypass is associated with the highest risk of mortality, aortic stump blowout, and graft occlusion of the available surgical options.
 - 8 Treatment of aortic grafts infections with graft excision and in situ reconstruction with rifampin-soaked Dacron has been associated with the highest rate of reinfection of the available surgical options.
 - 9 Treatment of aortic grafts infections with graft excision and in situ reconstruction with femoral vein is the most time-consuming surgical option, but is associated with the lowest risk of reinfection.
 - 10 Treatment of aortic grafts infections with graft excision and in situ reconstruction with cryopreserved human allograft has been associated with a risk of graft rupture and pseudoaneurysmal degeneration.
-

Vascular infections are among the most daunting conditions that a surgeon may encounter in clinical practice. Vascular infections may afflict native arteries and veins or vascular prostheses. Primary arterial infections of native arteries are rare, but highly lethal conditions.¹ Secondary infections of prosthetic vascular grafts, albeit rare, are seen more frequently and are often more challenging because of the adhesions, scarring, and inflammation in the redo operative field.² These infections commonly occur in a compromised patient population with significant chronic medical conditions and relative immune deficiency. The clinical presentations for vascular infections range from indolent infections detected incidentally to overt sepsis or hemorrhage.¹ The management of vascular infections is individualized, based on the clinical presentation and anatomic location of the vascular infection and the medical condition of the patient. In recent years, newer therapeutic adjuncts, such as covered stents and improved cryopreserved grafts, offer additional options to surgeons managing and treating arterial graft infections. However, the basic tenets of timely diagnosis, antibiotic administration, resuscitation, operative planning, surgical resection, and revascularization remain the mainstays of therapy in most cases.

DEFINITIONS AND PATHOGENESIS

Pathogenesis of Primary Arterial Infections

1 2 3 Arterial infections commonly result in aneurysms, or more correctly pseudoaneurysms since there

is disruption of the arterial wall in many infected aneurysms. Aneurysms or pseudoaneurysms related to infection are often loosely termed “mycotic aneurysms.” However, the term mycotic aneurysm was initially coined to describe an arterial aneurysm or pseudoaneurysm caused by a septic embolus from the heart that lodges in a distal artery to create a septic focus that injures the adjacent artery.³ Pre-existing aneurysms that are subsequently seeded by bacteremia are “infected aneurysms.” Arteries in which an atherosclerotic plaque becomes seeded develop “microbial arteritis.” “Traumatic infected aneurysms” describe those infected aneurysms or pseudoaneurysms that develop secondary to complications of iatrogenic or other trauma. “Infected aortitis” occurs when the aorta becomes infected by contiguous septic structures, such as vertebral osteomyelitis.³ For simplicity, we will utilize the term “primary arterial infection” to refer to all infected arterial infections that occur in the absence of prosthetic graft or stent material.

Infective endocarditis is no longer the major source of primary arterial infections. Arterial trauma, particularly due to intravenous drug use, appears to be the most prevalent cause.¹ Risk factors for primary arterial infections include trauma to the arterial wall, atherosclerosis, and pre-existing aneurysmal degeneration. In an autopsy study, Miller reaffirmed that many of infected aneurysms arise after pre-existing atherosclerotic lesions are seeded due to an episode of bacteremia, since 75% of the infected arteries had evidence of atherosclerosis in the resected specimen.⁴ In Miller’s study, 42% of arterial infections were located in the infrarenal aorta; the descending thoracic aorta was the next most common site of infection.⁴ Immune compromise by systemic conditions or medications, such as chronic steroid use, malignancy, human immunodeficiency virus syndrome, chronic hepatitis, or malnutrition, is a common theme among patients with primary arterial infections. Predisposing conditions have been identified in nearly 70% of patients with mycotic aneurysms.^{4–7}

Pathogenesis of Arterial Graft Infections

Prosthetic grafts are foreign bodies that are either seeded at the time of the operation, or become infected secondarily due to hematogenous seeding or contiguous infection.^{8–10} Data from the UK Small Aneurysm Trial suggest that contemporary rates of aortic graft infections after open aortic reconstruction are approximately 2%.¹¹ In his study of abdominal aortic aneurysms repaired in Washington State from 1987 through 2005, Vogel found that the 2-year rate of aortic graft infections was 0.19%.¹² Infrarenal endograft implantation is associated with infection rates of less than 1%.^{13–15} The infection rate of thoracic aortic endografts is less well defined due to smaller number of thoracic endografts, compared to infrarenal aortic endografts, but most authorities believe that the rates of thoracic endograft infection are similar to those described for infrarenal aortic endografts. No particular endograft design or fabric appears to alter the risk of graft infection.^{13–15}

Lower extremity prosthetic grafts are at the highest risk of infection, which probably relates to the abundance of skin flora in the groin and the proximity of the graft to the incision. Infections of grafts originating from or terminating at the femoral artery complicate 4% to 6% of cases.^{16,17} By comparison, carotid patches rarely become infected, with Mann reporting a single-center incidence of 0.8% over 20 years.¹⁸ Polytetrafluoroethylene (PTFE) may be somewhat more resistant to infection than Dacron, as it has less porosity to sequester microbes.¹⁹ Peripheral bare metal stents appear to be highly resistant to infection, with a presumed incidence of less than 0.1% based on isolated case reports.²⁰

5 Prosthetic material is at risk for becoming infected for several reasons. First, a 10,000-fold lower bacterial bioburden is required to cause a graft infection, relative to healthy tissue.²¹ Irregularly surfaced materials are also more likely to harbor microbes, as these surfaces create small pockets where shear stress is decreased to allow bacterial attachment.^{19,22} Also, the local inflammatory response to implants abrogates the local defense against infection. Instead of being inert, the prosthetic material acts as a potent activator of host defenses, which subsequently renders them less capable of defending the graft from infection. Multiple studies have shown contact with implants causes neutrophils to lose their ability to produce superoxide and reactive oxygen species, which are critical to their bactericidal activity.^{23,24} Finally, communities of bacteria form slime to create biofilms, protecting microbes from host defenses and antibiotics.^{19,22,25} Quorum-sensing is prevalent in biofilms, which decreases the virulence of microorganisms and makes them more difficult to eradicate by host defenses as the bacteria proliferate.²⁶ This is a critical step in the pathogenesis of prosthetic graft infections caused by *Staphylococcus epidermidis* (Fig. 88-1).^{19,21–26}

Figure 88-1. Proposed mechanism of *Staphylococcus epidermidis*-mediated graft infection.

MICROBIOLOGY

Primary Arterial Infections

For infected aortic aneurysms, blood cultures are negative in approximately one-fourth of subjects.⁴ Intraoperative cultures are more reliable, although intraoperative cultures may be negative in many cases due to improper culture techniques or preoperative antibiotic administration that precludes isolation of organisms.⁴⁻⁷ In other series, up to 40% of infected aneurysms had negative blood and/or tissue culture.⁵ The most frequent causative organisms vary by country. Hsu et al. found that 76% of primary aortic infections in Taiwan were due to *Salmonella* strains.⁷ Reports from the United States show that *Staphylococcal* species (*S. aureus* or *S. epidermidis*) are most prevalent, followed by *Escherichia coli*, *Streptococcal* species, and *Salmonella*. Anaerobic, mycobacterial, and fungal infections represent rare causes of arterial infections.^{4,6} European series are similar to the American experience, as Muller reported that 30% of infections in his series were related to *S. aureus* and *S. epidermidis*.⁵ In Muller's series, *Salmonella* was the next most frequent isolate, followed by *Aspergillus*, *Enterococcus*, *Streptococcus*, and *E. coli*.⁵ The causative organisms also appear to vary based on the artery involved. Infected femoral artery aneurysms are rarely true aneurysms, but are infected pseudoaneurysms related to prior catheterizations or intravenous drug use. Skin flora, such as *S. aureus* or *Streptococcal* species, are the predominant organisms isolated from infected femoral artery pseudoaneurysms.²⁷

Arterial Graft Infections

4, 6 For prosthetic graft infections of the aorta, the causal organism is frequently not identified.² It is believed that most aortic graft infections occur as a consequence of intraoperative contamination by skin flora. Other sources include erosions of the graft into adequate structures and contiguous infections that cross-contaminate the graft. The main organisms responsible for aortic graft infections are *S. aureus* and *S. epidermidis*, accounting for 30% to 55% of the prosthetic vascular graft infections.^{2,10,14,15} Other organisms include *Streptococcus*, gram-negative organisms, anaerobes, and fungal species.² Polymicrobial infections are present in one-third of subjects.² Fungal infections, particularly *Candida* species, are most frequently encountered with aortoenteric fistulas (AEF).² Anaerobic and fungal infections are also frequently associated with polymicrobial infections and sepsis.²

Prosthetic grafts infections involving the femoral artery are most often related to *Staphylococcal* species, which comprised 68% of the infections in one series.^{16,17} *Enterococcal* and polymicrobial infections were less frequent among femoral artery grafts.^{16,17} Endograft infections are predominantly caused by *Staphylococcal* species and other minor skin flora, such as *Propionibacterium*.^{14,15} Similarly, *Staphylococcal* species predominate in peripheral arterial stent infections, with over 85% of the case reports attributed to *Staphylococcal* species.²⁰ In a report on carotid artery prosthetic patch infections, Mann found that 58% were related to *Staphylococcal* infection, one-third had an unidentified source due to negative cultures, and the remainder had gram-negative infections, with one beta-hemolytic *Streptococcal* infection.¹⁸

CLASSIFICATION OF ARTERIAL GRAFT INFECTIONS

Arterial graft infections are classified based on the time since implantation, the relationship to a surgical site infection, and the extent of prosthetic involvement. Bunt's classification, devised in 1983, describes prosthetic vascular graft infections according to the anatomic segment of the graft that is infected. A P0 graft infection involves a cavitory graft, such as aortic graft or the aortic portion of an aortobifemoral graft. P1 infections describe infections of grafts whose entire course is extracavitary, such as a lower extremity bypass graft infection. A P2 infection occurs when the extracavitary portion of a graft with an intracavitary origin becomes infected. Infected femoral limbs of aortobifemoral bypass graft represent a P2 infection. P3 infections are those involving prosthetic patches, such as a carotid patch. Pertinent descriptive qualifiers include the presence of a graft-enteric erosion, a graft-enteric fistula, or an aortic stump infection (after removal of an infected aortic graft).²⁸

Early graft infections are defined as those occurring less than 4 months after graft implantation. The Szilagyi classification system classified early surgical site infections. Szilagyi I and II infections are superficial infections. Szilagyi III surgical site infections involve either native arteries or vascular graft material, which is most relevant to vascular surgeons.²⁹ The Szilagyi classification system was modified by Samson to further distinguish between different types of vascular infections.³⁰ Samson group 1 infections involve only the dermis, whereas group 2 infections extend into the subcutaneous tissues without graft involvement. Group 3 infections involve the graft, but not the arterial anastomosis. Group 4 infections involve an exposed anastomosis without bacteremia or anastomotic bleeding. Group 5 is the most serious type of infection, with an exposed anastomosis and associated bacteremia or bleeding.³⁰ Clinical management often varies significantly based on the extent of infection, according to these classification systems.

DIAGNOSIS

The diagnosis of primary arterial infection or prosthetic graft infection may be difficult due to the significant overlap of symptoms with other pathologies. While a thorough history and physical examination are essential, a high index of suspicion is critical to the diagnosis. Delays in diagnosis may have devastating consequences for the patient. Understanding some of the more common presentations of arterial infections can facilitate a timely diagnosis.

Common Clinical Presentations

Patients with vascular infections often present with non-specific symptoms of malaise, fever, and pain in the region of the infected artery or graft, which may be accompanied by elevations in erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP).⁶ These symptoms are most commonly associated with arterial infections caused by more virulent organisms, such as *S. aureus*, *P. aeruginosa*, *E. coli*, or polymicrobial infections. Arterial infections caused by lower virulence organisms, such as *S. epidermidis* or *Enterococcus*, are often even more indolent and may not be associated with local or systemic signs and symptoms.³¹ Peripheral arterial infections (primary or graft infections) may exhibit local symptoms, such as erythema, swelling, tenderness, or a sinus tract with purulent drainage.³¹ In contrast, local signs and symptoms are unlikely with infections of cavitory arteries or grafts.

If a primary arterial infection is suspected, the patient should be queried for potential sources of infection. Many patients with arterial or graft infections have a history of an antecedent infection, such as pneumonia or a urinary tract infection.⁶ A recent gastrointestinal illness may be a source of exposure to *Salmonella*.⁷ Other potential clues include a history or clinical stigmata of intravenous drug use or a recent invasive procedure, which could provide a mechanism for seeding of a native artery or graft.

Associated medical conditions may be cofactors in the pathogenesis of vascular infections. Any condition that produces relative immune compromise may predispose to primary arterial or graft infection. Examples include malignancy, human immunodeficiency virus syndrome, chronic hepatitis, malnutrition, and conditions that require immunosuppressive medications. Predisposing conditions have been identified in up to 70% of patients with mycotic aneurysms.⁴⁻⁷ Malignancy is especially relevant due to the association between *Clostridium septicum* arterial infections and malignancy.³² Symptomatic atherosclerosis is important to note since atherosclerotic plaques may become seeded by episodic bacteremia to create a primary arterial infection.

For patients with a history of a prior bypass involving the femoral artery, occult infections frequently present with an anastomotic pseudoaneurysm in the groin. Over 60% of femoral pseudoaneurysms are

ultimately found to harbor an occult infection.³³ Mertens found that 74% of patients with infected infrainguinal bypass grafts presented with a draining wound or sinus.³⁴ Infections with low virulence organisms, such as *S. epidermidis*, are less likely to be present with a draining sinus because the virulence of the organisms is insufficient to incite a vigorous inflammatory response to produce the sinus tract.³¹

Graft thrombosis is another clinical presentation for an occult graft infection. Graft thrombosis is believed to predispose to subsequent graft infection.^{35,36} The coagulated blood within a thrombosed prosthetic graft provides a rich media for the microorganisms to proliferate.³⁷ In addition, prosthetic materials are fomites that may harbor microorganisms. Some authors advocate removing occluded grafts when performing subsequent revascularization operations or amputations to prevent contiguous spread from the prior occluded grafts.^{35,36}

Gastrointestinal hemorrhage is a rare, but life-threatening presentation for graft infection that must be diagnosed expeditiously. Any patient presenting with gastrointestinal hemorrhage that has a history of prior aortic surgery, especially those with vascular prostheses, must have a rapid evaluation for an AEF. AEFs often present initially with a “herald bleed,” or a relatively small amount of gastrointestinal bleeding that temporarily abates prior to fatal exsanguination several hours or days later.³⁷⁻³⁹ The mortality rate for AEFs is 30% to 77%. Delay in diagnosis is often a contributing factor among patients who die from this condition. Approximately 75% of AEFs result from a communication between the aorta and the third or fourth portion of the duodenum.³⁷ The vast majority of AEFs occur in the setting of prior surgical or endovascular aortic reconstruction. Rarely AEFs occur as a complication of a primary aortic infection.⁴⁰ If a portion of the graft erodes through the adjacent bowel without suture line involvement, gastrointestinal bleeding results from intestinal mucosal irritation. This phenomenon is termed “graft-enteric erosion.”⁴¹ Graft-enteric erosions are often discovered incidentally during surgery to excise an infected aortic graft.

Ureteral obstruction can occur due to a mechanical complication during the tunneling of an aortofemoral limb or as a consequence of the inflammatory reaction associated with an infected aortofemoral limb. Ureterohydronephrosis is strongly associated with aortic graft infections. Wright et al. found that the presence of a urologic complication after aortoiliac arterial reconstructions was associated with a fourfold increase in the risk of graft complications, including pseudoaneurysms, limb thrombosis, AEFs, and overt graft infections.⁴² Ureteral complications are typically asymptomatic, so ureterohydronephrosis is often discovered incidentally during imaging studies for other indications and should alert the physician to the possibility of a graft infection.

Imaging for Vascular Infection

The history, physical examination, and laboratory findings for primary arterial infection or graft infections are often nonspecific, so imaging plays a pivotal role in establishing a diagnosis. Although advances in imaging techniques have improved the sensitivity and specificity significantly, no single modality is perfect. Confirming a physician’s suspicion of occult infection with a low-virulence organism remains a challenge in many cases. Understanding the advantages and disadvantages of each imaging modality will allow the surgeon to choose the most appropriate examination, or combination of imaging studies, to optimize the diagnostic yield.

Computed Tomography (CT) and Computed Tomographic Angiography (CTA)

CT and CTA are the preferred imaging modalities for suspected aortic graft infections in most centers. CT is readily available in most hospitals, and standard protocols enable most centers to duplicate the diagnostic sensitivity achieved at centers of expertise. Contrast allergy, contrast-induced nephropathy, metal artifact, and radiation exposure are shortcomings of CT, but the benefit outweighs the risk in most cases. The addition of oral contrast agents can help to define the association with enteric structures if an AEF is suspected. Findings suggestive of graft infection on CT or CTA include inflammatory changes in the soft tissues surrounding the graft (Fig. 88-2), thickening of the bowel adjacent to vascular structures, loss of tissue planes around the artery or graft, and perigraft or periarterial air or fluid (Figs. 88-3 and 88-4).^{43,44} The sensitivity and specificity of CT for the diagnosis of aortic graft infections may be as high as 95% and 88%, respectively,⁴⁴ although the diagnostic accuracy varies depending upon the organism and severity of the infection. The sensitivity and specificity for low-grade, indolent infections may be as low as 55% and 100%, respectively.^{45,46} The presence of either fluid or air significantly enhances both the sensitivity and specificity of CT scans for detecting late graft infections (>4 months postimplantation).^{43,44} Early graft infections (<4 months postimplantation) present a particular

challenge for diagnosis. Perigraft air is a normal finding in the periaortic tissues for 2 months after open aortic reconstruction and should not be considered indicative of an aortic graft infection.^{47,48} Similarly, a small amount of perigraft fluid is normal for 3 months after arterial reconstruction.⁴³ After endovascular aortic aneurysm repair, Sawhney found that air was visualized in the aneurysm sac, surrounding the endograft, in 58% of patients on early postoperative CTA.⁴⁹ The air is introduced during endograft deployment and dissipates over a period of weeks after surgery.

Figure 88-2. CT scan demonstrating loss of tissue planes around the artery (A), with small foci of air (B) suggesting a mycotic aneurysm.

Duplex Ultrasonography

Duplex ultrasound offers a relatively safe and inexpensive tool for evaluating native arteries and bypass grafts for signs of infection. Ultrasound circumvents the risks of contrast allergy, contrast-induced nephropathy, and radiation associated with CT. The main drawbacks of ultrasound are the lack of availability in some centers of skilled ultrasound technicians capable of arterial imaging. Overlying structures, particularly bowel gas and the lungs, and body habitus can also obscure visualization and limit the efficacy of ultrasound evaluations within the chest or abdomen.⁴³ Findings on duplex ultrasound that are suggestive of infection include the presence of a pseudoaneurysm, hematoma, soft tissue masses, and perigraft gas and fluid collections. A “halo sign” surrounding an infected aortofemoral limb is a hypo-acoustic shadow surrounding the graft that is indicative of perigraft fluid consistent with graft infection.⁵⁰

Magnetic Resonance Imaging (MRI)

MRI offers some theoretical advantages over CTA for the diagnosis of vascular infections, including the avoidance of radiation and contrast-induced nephropathy. There are also clear disadvantages to MRI that have limited its utility in diagnosing graft infections. MRI studies for graft infection are time-consuming, and MRI is contraindicated for patients with certain metal implants.⁴⁷ The sensitivity and specificity for graft infection is highly variable between institutions. MRI may be as useful as CT scan in the diagnosis of arterial infections at centers with expertise with MRI for arterial infections. In a study of 40 patients with suspected arterial graft infections, Shahidi found that the sensitivity, specificity, positive predictive value, and negative predictive value of MRI were 68%, 97%, 95%, and 80%, respectively.⁵¹ MRI may detect small collections of biofilms, the hallmark of *S. epidermidis* infections, which are notoriously difficult to diagnose.⁴⁷ MRI creates a low-intensity “halo” around infected grafts on T₁ imaging, while also creating a hyperintense signal on T₂-weighted images.^{47,52} Since gadolinium is not required, MRI may be useful in patients with chronic renal insufficiency. MRI is plagued by some of the same limitations as CT in detecting early graft infections since air and fluid are normal findings on MRI for 2 to 3 months after graft implantation.⁵³

Figure 88-3. CT scan demonstrating perigraft fluid surrounding a prosthetic aortic graft as a sign of an aortic graft infection.

Figure 88-4. CT scan demonstrating perigraft air (A) surrounding an endograft as a sign of graft infection associated with a possible aortoenteric fistula.

Leukocyte Scintigraphy

Leukocyte scintigraphy may be performed using either ¹¹¹Indium- or ^{99m}Technetium-labeled leukocytes to localize infection within the arterial wall or graft. A theoretical advantage of leukocyte scintigraphy is the diagnosis of indolent infections with low-virulence organisms for which the symptoms are most ambiguous. Unfortunately there are numerous pitfalls to this modality. Leukocyte scintigraphy is time-consuming, labor-intensive, and prone to false-positive results due to undesired cross-labeling of platelets that may bind to grafts.^{54,55} Uptake of the radionuclide-labeled white blood cells requires intact chemotaxis and a minimum total white blood cell count of 2,000/ μ L.⁵⁵ The net effect of these issues is that the sensitivity and specificity for tagged white blood cell scanning is highly variable between institutions, with sensitivity and specificity both ranging between 50% and 100%.^{51,54,55}

Single Photon Emission Tomography (SPECT) Scanning

SPECT scanning, when combined with CT scanning, may enhance the specificity of leukocyte scintigraphy in the detection of vascular infections.^{56,57} While there are limited data available at this time, the early results appear promising. Erba recently evaluated SPECT-CT in 55 subjects with suspected vascular graft infections. SPECT-CT reduced the number of false positives by 37%, compared to CT alone. The sensitivity and specificity of SPECT-CT was 100%, which was superior to SPECT or CT alone.⁵⁷

Fluorodeoxyglucose Positron Emitting Tomography (FDG-PET)

FDG-PET utilizes glucose labeled with ¹⁸fluoride, which is utilized by cells proportional to their metabolic activity. Initially, this technique was utilized to detect occult metastases in oncology patients. Recently the protocols have been adapted for the detection of occult arterial infections.^{58,59} FDG-PET can be advantageous in diagnosing endograft or peripheral stent infections since the images are less prone to metal artifact. Compared with leukocyte scintigraphy, FDG-PET offers the advantages of shorter examination times, less radiation exposure, higher resolution, and improved interobserver agreement.^{60,61} Unfortunately there is a high false-positive rate for diagnosing arterial graft infections

because of the inflammatory response associated with prosthetic grafts.⁵⁸ Poor uptake of the FDG-glucose can also yield nonspecific results, which is a limitation of using this test in diagnosing low-virulence infections. While the sensitivity and specificity of FDG-PET alone are inferior to CT scan alone, combining FDG-PET with CT scanning markedly improves the localization of infection and the sensitivity and specificity of the examination. Using the approach, Spacek reported a diagnostic accuracy exceeding 95% in a series of 95 grafts.⁵⁹ For FDG-PET-CT, Bruggink reported a sensitivity, specificity, positive predictive value, and negative predictive value of 93%, 70%, 82%, and 88%, respectively, which was superior to FDG-PET alone.⁶⁰ Further study is required to define the threshold for a positive FDG scan in the setting of cavitory arterial infections.^{61–63} Drawbacks of the fusion technology include longer study times and increased radiation exposure. Furthermore, expertise with FDG-PET-CT techniques is not widely available. Despite these limitations, some authorities foresee the combined modality becoming the study of choice in the future.⁶¹

Adjunctive Diagnostic Modalities

Arteriography, endoscopy, and image-guided biopsy should be viewed as adjunctive diagnostic modalities that have a limited role in diagnosing graft infections. Arteriography may be useful in planning reconstruction. Rarely, an occult AEF can be discovered with angiography by filling of the enteric structure.⁶⁴ Esophagogastroduodenoscopy (EGD) is typically performed to exclude other sources of upper gastrointestinal hemorrhage in a patient with a suspected AEF. EGD was successful in diagnosing AEF in approximately 25% cases in one small series of primary AEFs.⁴⁰ In spite of the low diagnostic yield, the authors recommended endoscopy in hemodynamically stable patients with a suspected AEF because of the devastating consequences of a missed diagnosis. Image-guided biopsy of the fluid or rind surrounding the affected vascular structure has been advocated when the diagnosis of graft infection is equivocal.^{65,66} This approach could potentially distinguish between patients with benign early postoperative perigraft gas versus an early graft infection. However, sufficient sampling is difficult to achieve in all cases, as the tissue is often fibrotic and in close proximity to other major vascular structures and bowel.⁶⁶ Further study will be required to clarify the role of this modality in the evaluation of arterial infections.

CONSERVATIVE MANAGEMENT

Primary Arterial Infections

Hsu et al. provided insight on the outcome of conservative management of subjects with primary aortic infections.⁶⁷ Hsu examined 22 subjects with infected aortic aneurysms with perceived contraindications to surgery. The predominant organism in the cohort was *Salmonella*, with two-thirds of subjects having infections of the abdominal aorta. All subjects received culture-specific intravenous antibiotics for at least 6 to 8 weeks, or until normalization of white blood cell count, daily temperatures, and C-reactive protein levels. After the acute phase treatment, oral antibiotics were continued indefinitely. In Hsu's series, the inhospital mortality was 50% due to rupture or sepsis. The 1-year survival rate was 32%. Patients with *Salmonella* infections had a lower aneurysm-related mortality rate than patients with non-*Salmonella* infections.

Arterial Graft Infections

Calligaro advocated for complete or partial prosthetic bypass preservation in subjects with severe comorbidities precluding surgical repair.⁶⁸ Over a 20-year period, 51 extracavitary grafts (aortofemoral limbs or lower extremity bypasses) were treated with graft preservation and aggressive wound management without surgical graft resection. When wounds were present, aggressive debridement of all necrotic tissue and exudate surrounding the artery was performed. Nine cases utilized adjunctive muscle flaps to aid healing. Povidone-iodine 1% or antibiotic-soaked dressing changes were performed three times a day. With this regimen, 2 of 51 patients (4%) experienced major hemorrhage from the infected graft at 3 and 12 months after presentation. Eleven of the patients (22%) failed the treatment regimen, with nonhealing wounds or recurrent infections requiring total graft excision. Thirty-two subjects (63%) were ultimately treated successfully. Calligaro concluded that conservative management of extracavitary grafts is an acceptable option in the absence of sepsis or hemorrhage, especially when graft excision and revascularization is not feasible due to patient comorbidities. *Pseudomonas* infections, however, were particularly prone to failure with this regimen.

Building on the early reports of graft preservation therapy, subsequent reports have emerged utilizing vacuum-assisted negative pressure therapy with antibiotics and wound debridement to preserve extracavitary grafts with Szilagyi III wounds.^{69,70} Wound healing with these regimens have ranged between 82% and 91% with excellent graft preservation rates.^{69,70} Episodes of hemorrhage remain an issue with this approach,⁶⁹ and the failures have been associated with *Pseudomonas*.^{69,70} Based on these reports, it appears that carefully selected patients with early infections involving extracavitary grafts may be treated without surgical graft excision with acceptable results.

Calligaro et al. used a nonoperative approach in six patients with intracavitary graft infections with a hostile abdomen or severe medical comorbidities.⁷¹ All subjects underwent either open or percutaneous placement of drains along the graft with instillation of 10 mL of 1% povidone-iodine in 100 mL of normal saline or antibiotics (neomycin or a cephalosporin) three times a day. All subjects were treated concurrently with culture-directed intravenous antibiotic therapy for 6 weeks, followed by 6 months of oral antibiotic therapy. Of these 6 subjects, only one died due to sepsis. One patient ultimately required total graft excision and survived. The remaining patients (66%) were alive at last follow-up. These authors showed that in highly selected patients, conservative management can have reasonable outcomes. In the absence of larger series, this approach should be reserved for patients who are not reasonable candidates for graft excision.

SURGICAL MANAGEMENT OF AORTIC ARTERIAL AND GRAFT INFECTIONS

Surgical treatment is based upon the central tenets of appropriate resuscitation, preoperative planning, resection of all infected material and tissue, and arterial revascularization. The optimal method of arterial reconstruction remains unresolved, as few direct comparisons between approaches have been published. Based on our extensive institutional experience with a variety of techniques, we have concluded that no single approach is suitable for all patients. We advocate tailoring the treatment algorithm based on each patient's clinical presentation and the local surgical expertise.

Aortic Infections Presenting with Hemorrhage or Sepsis

A minority of patients present with septic or hemorrhagic shock. For these patients, rapid intravenous access and resuscitation are essential prior to emergent surgery. In the authors' experience, the complexity of the operations required to manage these patients mandates a rapid CTA to obtain essential anatomic information. It is recognized that some of these patients will have either acute kidney injury or chronic kidney disease, but managing the life-threatening complications of the aortic graft infection outweighs the risk of contrast-induced nephropathy. Ideally, blood and wound cultures are obtained prior to the administration of broad-spectrum gram-positive and gram-negative antibiotic therapy. The surgical approach to managing patients presenting with hemorrhage or sepsis should be individualized based on the patient's anatomy and the expertise of the surgeons.

Endografting as Bridge Therapy

Endografts are being used with increasing frequency as a method to temporize hemorrhage in patients with aortoenteric or aortobronchial fistulas.^{38,39,72,73} When the anatomy permits, endografting may temporarily prevent exsanguination and allow time for resuscitation, medical stabilization, and further investigations to plan definitive surgery.⁷² Endografting should not be viewed as definitive therapy since recurrent hemorrhage occurs in majority of cases without further surgical treatment.^{39,73} Definitive surgery should be planned within 2 weeks of endografting, since most episodes of recurrent bleeding occurred greater than 2 weeks after initial endografting.⁷³ The exception to this principle is an aortobronchial fistulae for which endografting may be viewed as definitive therapy.³⁸

Definitive Surgery for AEF

Definitive surgery for an AEF involves resection of the infected graft, repair of the enteric defect, and revascularization of the lower extremities. The most appropriate surgical approach to achieve these goals has been the focus of considerable debate. For decades, the most common approach to AEFs was total graft excision with ligation of the infrarenal aortic stump and extraanatomic bypass.⁷⁴⁻⁷⁸ In recent years, a variety of groups have touted the merits of in situ reconstruction of the aorta after graft excision, using a variety of conduits. The advantages, disadvantages, and technical details of these approaches are discussed later in the chapter (see "Aortic Infections in the Stable Patient").

Aortic Ligation and Extraanatomic Bypass for AEFs

In stable patients with a small herald bleed caused by an AEF, Reilly et al. at the University of California-San Francisco advocated staging of the two component operations at an interval of several days to minimize the physiologic impact on the patient.⁷⁵ The first stage of this approach consists of performing an axillobifemoral bypass or bilateral axillary–popliteal bypasses, followed several days later by resection of the infected graft with aortic stump closure. In the patient with ongoing bleeding or hemodynamic instability, a staged approach is not feasible. Reilly reported a 26% mortality rate with the staged approach, compared to 43% for the traditional, nonstaged.⁷⁵ A subsequent study by Seeger reported a 19% treatment-related mortality rate.⁷⁶ In addition to a high mortality rate, this approach is plagued by a significant risk of aortic stump blowout (9%), reinfection of the extraanatomic bypass graft (16%), and major amputation (16%).⁷⁵

In Situ Aortic Reconstruction for AEFs

In response to the sobering results associated with the traditional approach, in situ aortic reconstruction has been touted as a relatively simple and effective alternative.^{80–84} Oderich et al. from the Mayo Clinic reported their results using in situ rifampin-soaked grafts in 54 patients with aortic graft-enteric erosions or fistulae.⁸⁰ In their series, operative mortality was 9%, and graft reinfection occurred in 4%. A subsequent multicenter study of 37 patients with AEFs treated with either in situ prosthetic grafts ($n = 9$), extraanatomic bypass ($n = 25$), or endografting ($n = 3$), reported a 30-day mortality rate of 43% for in situ reconstructions.⁸² In that series, 3 of 11 (27%) long-term survivors with in situ grafts developed reinfection of the in situ graft, which was universally fatal.

Alternative conduits for in situ reconstruction for AEFs include cryopreserved aortoiliac allograft and femoral vein. Harlander-Locke et al. published a multicenter experience with 220 patients with aortic graft infections treated with in situ cryopreserved aortoiliac allograft, which included 33 patients with AEFs.⁸³ The reinfection rate in patients presenting with AEFs was 12%. In situ repair with autogenous femoral vein is not appropriate in the unstable patient due to the time required for femoral vein harvest, but may be reasonable in the stable patient with a herald bleed due to an AEF. Valentine reported a 42% mortality rate in 24 patients treated with in situ femoral vein for AEFs and graft-enteric erosions, so femoral vein may not offer any advantage over the alternative conduits for AEFs.⁸⁴

Aortic Infection with Sepsis

Sepsis caused by an aortic infection poses a challenge because temporizing with an endograft is not an option since the septic focus is not eliminated. In unstable patients, CT-guided percutaneous drainage may be a reasonable option for source control if there is a large perigraft fluid collection. In a series of 23 patients with graft infections, Belair et al. found that percutaneous drainage was associated with improved perioperative mortality, compared to surgery alone.⁸⁵ In the absence of a large perigraft fluid collection for percutaneous drainage, graft excision with extraanatomic bypass is the most reasonable approach.

Aortic Infections in the Stable Patient

Preoperative Evaluation

The incidence of coronary artery disease is high in surgical series of arterial infections, especially in subjects with infected endografts.^{2,6,14} Thus, a thorough cardiovascular history, physical examination, 12-lead electrocardiogram, and echocardiogram should be obtained to evaluate for heart failure, valvular dysfunction, and pulmonary hypertension. These investigations may reveal a history of active cardiac conditions that may modify the type of operation selected or preclude surgery. Only rarely is stress testing or coronary arteriography indicated since coronary revascularization is usually contraindicated in the context of an active infection. However, this information may alter the surgical plan, provide valuable information for the anesthesiologists, and guide discussions with the patient or family regarding the expected outcomes. Pulmonary evaluations are rarely undertaken, as this information seldom alters the management of the patient. Only those patients with the most severe pulmonary insufficiency may benefit from formal testing to guide perioperative management.⁸⁶

Operative planning is greatly facilitated by a preoperative CTA to define the arterial anatomy. Angiography of the lower extremities is reserved for cases when a concurrent infrainguinal bypass is considered likely. Noninvasive measurements of distal perfusion and lower extremity vein mapping should be performed. Ankle-brachial indices (ABIs) may forewarn the surgeon of the potential for infrainguinal revascularization after graft excision and aortoiliac reconstruction. Mapping of the

bilateral greater saphenous veins and femoral–popliteal veins is essential if an autogenous conduit is contemplated. Femoral–popliteal veins with a diameter of less than 6 mm or evidence of vein wall sclerosis are inadequate for aortoiliac reconstruction.²

Anesthetic Considerations

Operations to excise infected aortic grafts are technically challenging, lengthy, and prone to a large volume of blood loss. The importance of a quality anesthesia team in managing these challenges cannot be over-stated. Hypothermia, hypovolemia, and intraoperative anemia must be assiduously avoided with the use of warming blankets, warmed resuscitative fluids, warm ambient operating room temperature, and a low threshold for blood and crystalloid replacement. The blood bank should be prepared to provide fresh-frozen plasma, cryoprecipitate, or platelets on short notice if coagulopathy develops. Culture data are often not available at the time of operation, so broad-spectrum antibiotic coverage for gram-positive, gram-negative, and anaerobic organisms should be redosed throughout the operation.

Aortic Ligation and Extraanatomic Bypass Versus In Situ Reconstruction

A major advantage of graft excision with extraanatomic bypass is the removal of all prosthetic graft material from the infected operative field. This approach also obviates the need to procure an aortoiliac allograft. Finally, use of an extraanatomic bypass circumvents any reticence a surgeon may have with harvesting femoral veins since some surgeons are not familiar with the technique. The obvious pitfalls of this approach are the risk of aortic stump blowout, reinfection of the extraanatomic bypass graft, and poor long-term patency of the extraanatomic reconstruction. In situ reconstruction is appealing because it avoids the risk of aortic stump blowout and the poor long-term patency of extraanatomic bypasses. For patients with insufficient infrarenal aorta for a secure three-layer closure, in situ may be the only reasonable option. Reinfection of new graft is the obvious risk of this approach. In the following sections, we will offer technical suggestions for performing these complex operations and summarize the published results for each approach.

Aortic Graft Excision

Common to each of the described surgical approaches to aortic graft infection is the need for complete graft excision. For graft excision, aortic exposure can be performed via a transperitoneal or retroperitoneal approach. Proximal control of the infrarenal aorta can be challenging in a redo operative field, so the surgeon should be prepared to obtain proximal control of the aorta at the suprarenal or supraceliac level. When treating an AEF, we always obtain either suprarenal or supraceliac aortic control prior to mobilizing the duodenum since there may be uncontrolled hemorrhage in the absence of proximal aortic control. Balloon control is another useful adjunct in cases of severe inflammation or scarring.⁵⁰ The left renal vein may be densely adherent to the graft or the native aorta, which may necessitate its division to gain access to the aorta near the renal arteries. Once proximal control is obtained, distal control of the bilateral common iliac arteries should ensue, unless these arteries are occluded. When excising an aortofemoral graft, the femoral limbs should be controlled in the abdomen to facilitate their removal. Removal of aortofemoral grafts requires considerable dissection in the groins for control of the prosthetic graft limbs and native common femoral, superficial femoral, and profunda femoris arteries. Femoral exposure may be performed through an incision directly over the femoral limb or incisions lateral to the sartorius muscle. The lateral incision avoids some of the prior scarring and may preserve soft tissue for arterial coverage. Systemic heparin is administered prior to cross-clamping, and the graft is removed in its entirety. Any arterial tissue that appears to be abnormally friable is probably infected and should be debrided. Remnants of graft and arterial tissue should be sent for Gram stain, culture, and sensitivity testing. A critical adjunct is wide debridement of the retroperitoneum, which is believed to decrease the residual bacterial bioburden that will predispose to recurrent infection. After completing graft excision and debridement, closure of the aortic stump or in situ aortoiliac reconstruction may ensue.

Extraanatomic Bypass

For stable patients, staging of the extraanatomic bypass and graft excision should be considered, as proposed by Reilly.⁷⁵ The first stage of this approach consists of performing an axillobifemoral bypass or bilateral axillary–popliteal bypasses, meticulously avoiding any infected or contaminated planes when tunneling the new grafts. The second stage consists of aortic graft excision, retroperitoneal debridement, and aortic stump closure. Aortic stump closure requires a meticulous three-layer closure of

the aorta. The first two layers consist of two layers of nonabsorbable polypropylene suture; a vertical mattress suture, followed by running “baseball” suture. The final layer is an omental wrap secured with sutures.⁷⁵ When staging the extraanatomic bypass and graft excision, the optimal time interval between the two operations has not been defined. It has been our experience, however, that the presence of both an aortobifemoral bypass and an extraanatomic bypass creates competitive flow between the grafts that often results in thrombosis of the extraanatomic bypass graft. To minimize the risk of interval graft thrombosis, patients are anticoagulated with intravenous unfractionated heparin between operations, and a short (1 to 3 days) time interval (usually 1 to 2 days) between the two operations is planned. If the two operations are performed at the same operative setting, the clean portion of the procedure (the extraanatomic bypass) is performed prior to the infected portion of the case (graft excision) whenever feasible to minimize the risk of bacterial inoculation of the new graft.

The outcomes for graft excision with extraanatomic bypass have been sobering. In their landmark review, Yeager and Porter reported an average mortality rate of 21% with an average amputation rate of 11% and recurrent infection rate of 18%.⁷⁷ In a series of 36 patients with aortic graft infections, Seeger et al. subsequently reported a similar mortality rate (overall treatment-related mortality rate of 19%), but a lower rate of reinfection and aortic stump blowout (2.8% incidence of each complication).⁷⁶ Seeger noted that the patency of the extraanatomic bypasses was directly related to the type of graft configuration. Axillobifemoral bypasses had a primary patency of 75% at 41 months, whereas the primary patency for axillopopliteal bypasses was 0%. Similar results have been observed using this approach in treating infected abdominal aortic aneurysms. Lee reported a series of 28 patients with infected abdominal aortic aneurysms treated with aortic resection plus either in situ repair ($n = 13$) or extraanatomic bypass ($n = 15$).⁸⁷ Lee observed a 27% mortality rate for the cohort receiving extraanatomic bypass in this nonrandomized study.

In Situ Reconstruction with Cryopreserved Arterial Allografts

Experience with allograft replacement of primary or secondary arterial infections began with Alexis Carrel more than a century ago.⁸⁸ Difficulties with procurement and preservation resulted in poor quality control. Allografts were largely abandoned until their resurrection for the treatment of infectious pathologies of the ascending aorta in the 1980s.⁸⁹ Initial positive experience resulted in more widespread use, including the treatment of infected infrarenal aortic graft infections.⁹⁰ Initially, local tissue banks were responsible for procuring, preserving, and allocating allografts for clinical use. This resulted in considerable variability in the processes of preparing and storing the product, which may have impacted the quality of the product. Currently these processes have been centralized in both North America and Europe with primary suppliers of the cryopreserved allografts.

The primary advantage of cryopreserved allografts is its resistance to infection, which is substantiated by recurrent infection rates ranging between 0% and 3.6%.^{83,90–94} Primary patency was 97% at 5 years in a multi-institutional registry, which is comparable to other conduits for in situ reconstruction.⁸³ The primary disadvantages of cryopreserved allograft in the early experience with this conduit were graft rupture and pseudoaneurysm formation. Newer cryopreservation techniques have improved the preservation of the arterial collagen matrix, decreasing the incidence of graft rupture and pseudoaneurysmal dilation. However, it is not clear that these issues have been fully resolved. Vogt et al. reported an allograft complication rate of 16% in a cohort of 43 implants, including one intraoperative rupture and three late ruptures (> 30 days after implantation).⁹² In a multicenter registry of cryografts, 24% of patients experienced major complications, including eight ruptures and six pseudoaneurysms.⁸³ The most frequent complication, however, was persistent sepsis, occurring in 17 subjects. Other disadvantages of cryopreserved allograft include the cost of the grafts (approximately \$18,000 per aortoiliac segment).⁸⁰ Moreover, these grafts are not readily available in most centers, making it less practical for infected pathologies complicated by hemorrhagic or septic shock.

In response to the early complications, Vogt recommended several techniques to prevent early adverse outcomes.⁹² These included proper timing of the allograft thawing and ligation of the allograft side branches with polypropylene suture that incorporates a portion of the allograft wall. Tension on the anastomoses must be avoided, and reinforcement of the anastomosis with circumferential allograft strips and gentamycin-impregnated fibrin glue is also recommended.

In Situ Reconstruction with Rifampin-Soaked and Silver-Impregnated Grafts

Rifampin shows unique activity against *S. epidermidis* biofilms, making it an excellent choice for prosthetic graft infections.⁹⁵ Rifampin-soaked Dacron grafts (600 mg rifampin in 250 mL of normal saline, soaked for 30 minutes) with omental wrapping has been shown to have variable resistance to

recurrent infection, ranging between 4% and 11.5%.^{80,81} Recurrent infections have been fewer when treating AEFs, compared to prosthetic graft infections. Primary patency is also excellent, ranging between 89% and 92%, with limb salvage rates of 100%.^{80,81,96} Circumferential omental wrapping of the grafts is a critical technical adjunct to decrease the risk of reinfection.⁸⁰

Silver-impregnation relies upon the ability of silver to adsorb gram-positive and gram-negative bacterial membranes, resulting in disruption of the membrane and cell lysis. There has been no reported bacterial resistance to silver.⁹⁷ It is theorized that silver-impregnated grafts would have activity against *E. coli* and methicillin-resistant *S. aureus*, which would be an improvement over rifampin-soaked grafts.⁹⁸ The limited clinical data suggest that silver-impregnated grafts are not equivalent to rifampin-soaked grafts since the reinfection rate was 15.7% in a single-center series in France.^{99,100}

In Situ Reconstruction with Autogenous Femoral Vein

Autogenous femoral vein was proposed as an alternative conduit for in situ reconstruction for infected aortic grafts in the early 1990s.¹⁰¹ Clagett described creating a “neoaortoiliac system” using femoral veins harvested from both legs. The proposed advantages of femoral vein include an innate resistance to infection and excellent long-term patency, which is borne out by the two largest series to date using femoral vein. Ali reported 187 neoaortoiliac reconstructions using femoral vein.² The 30-day mortality for this approach (10%) was not significantly different from other in situ reconstructions for graft infection. Predictors of mortality included preoperative sepsis and infection with *Candida glabrata*, *Klebsiella pneumonia*, or *Bacillus fragilis*. Reinfection occurred in 5%. Primary patency was 81% at 72 months. Daenens reported similar outcomes using femoral vein, including an 8% inhospital mortality rate.¹⁰² Daenens group observed no reinfections and no cases with aneurysmal degeneration of the femoral vein graft. The 5-year primary patency was 91% with a limb salvage rate of 98%.

The major pitfall of using femoral vein for in situ reconstruction is the time required to harvest the veins. Although many surgeons have not had formal training in the technique for harvesting femoral veins, it is well within the capability of any vascular surgeon. The technique is described in detail elsewhere.¹⁰³ Briefly, femoral veins are harvested using an incision extending along the lateral edge of the sartorius muscle from the anterior superior iliac spine to the medial condyle of the femur. The sartorius muscle is reflected medially to preserve the segmental blood supply of the sartorius. Collateral vessels from the superficial femoral and popliteal arteries should be preserved during vein harvest, especially in the setting of known superficial femoral artery occlusive disease.¹⁰³ The saphenous nerve should be avoided to prevent postoperative neuralgia. The femoral vein is harvested from its confluence with the profunda vein to the knee joint to provide a length of vein required to replace an aortobifemoral bypass graft. All side branches greater than 3 mm in diameter are doubly ligated, rather than suture-ligated, since the latter may tear the wall of the vein graft. The femoral vein is divided flush with the profunda vein to avoid creating a blind stump that could serve as a nidus for thrombus formation and subsequent pulmonary embolism. The vein is then everted in its entirety, with the intimal layer on the outside, to allow excision of the venous valves. After reversion, the graft is distended and any defects are repaired with 6-0 or 7-0 polypropylene suture. The graft is used in nonreversed orientation to improve the size match at the aortic and femoral anastomoses.

Among clinicians who are not familiar with using femoral vein for aortoiliac reconstruction, there appears to be reluctance based on concerns with any venous morbidity associated with harvesting the femoral vein. Our group has extensively studied this issue.^{104,105} In the early postoperative period, there is a risk of venous congestion that may produce lower leg compartment syndrome requiring fasciotomy. Early in our experience with deep vein harvest, fasciotomy was required in 17% of limbs, although many of those fasciotomies were “prophylactic.”¹⁰⁴ With additional experience, our tolerance for acute leg swelling has increased, so fasciotomy is now rarely performed. Two preoperative predictors of a higher probability of fasciotomy were identified: concurrent harvesting of the greater saphenous vein in the same limb and a low ankle-brachial index (<0.55) in the harvested limb. Prior harvest of the ipsilateral greater saphenous vein was not a risk factor for requiring a fasciotomy. Venous collaterals develop over time to normalize venous physiology in most patients, so long-term venous morbidity is minimal. One-third of patients experience mild chronic leg swelling, and the remainder are asymptomatic.¹⁰⁵ To our knowledge, no limbs have developed venous ulceration as a consequence of femoral vein harvest.

Comparisons of Arterial Reconstruction Methods for Aortic Arterial Infections

There is a dearth of direct comparisons of the various surgical options for managing graft infections in the literature. Over the past decade, there has been a trend toward various types of in situ

reconstructions due to the inferior patency of extraanatomic reconstructions and the risk of aortic stump rupture.⁷⁴⁻⁷⁸ O'Connor performed a systematic review of the literature to compare the various methods of reconstruction, comparing extraanatomic bypass, rifampin-soaked prostheses, cryopreserved allografts, and autogenous venous reconstructions.¹⁰⁶ Adverse events were more than 50% more frequent with extraanatomic bypass, compared to in situ reconstruction. The lowest event rates were noted with rifampin-soaked prosthetic bypasses. Early and late mortality was most likely after extraanatomic bypass. Autogenous venous reconstructions provided the lowest rate of reinfection, followed closely by cryopreserved allografts. Conduit failure was most likely with extraanatomic bypasses. The patient numbers were too low to compare the patency of rifampin-soaked bypasses with other reconstructions. Major amputation was most likely with either extraanatomic bypass or autogenous venous reconstructions. [Table 88-1](#) summarizes the authors selected studies reporting the outcomes of various reconstructions in aortic infections.

NONAORTIC ARTERIAL AND GRAFT INFECTIONS

Lower Extremity Arterial Infections

Lower Extremity Graft Infections

The nonoperative management of Szilagyi III wounds was described previously. Older studies show that lower extremity bypass graft infections carry a postoperative major amputation and mortality rate of nearly 50% due to the underlying atherosclerotic disease burden.¹⁰⁷ These patients often do not have other conduit suitable for bypass, which is a major impetus for graft preservation strategies for infected extremity bypass grafts. The use of local debridement with adjunctive vacuum-assisted closure and muscle flaps has yielded promising results. Siracuse cited an estimated 1-year limb salvage rate of 71%, which was attributed to the graft preservation techniques described above.¹⁷

Cryopreserved human allograft veins have been touted as an alternative if a prosthetic bypass graft must be removed for infection. Unfortunately, human allograft veins have yielded relatively poor results. In a series of bypasses for critical limb ischemia using cryopreserved greater saphenous vein, primary patency at 1 and 3 years was 27% and 17%, respectively.¹⁰⁸ Amputation-free survival at 1 and 3 years was 43% and 23%, respectively. Cadaveric vein grafts are expensive, ranging between \$7,000 and \$7,500. In view of the outcomes and cost, the use of cryopreserved veins must be weighed against the outcomes of graft preservation techniques on a case-by-case basis.

Infected Common Femoral Artery Pseudoaneurysms

The management of infected common femoral artery pseudoaneurysms diverges from the management of infected pseudoaneurysms in other anatomic locations. The most frequent clinical scenarios involve infection after a history of recent arterial catheterization or intravenous drug abuse. The incidence of infection after cardiac catheterization is less than 1%, although the use of arterial closure device increases the risk due to the presence of a foreign body.¹⁰⁹ Aggressive debridement, removal of the closure device, and revascularization remains the mainstays of therapy. In situ repair with autogenous greater saphenous or femoral vein is preferred if arterial replacement is necessary.^{27,110} A rotational muscle flap may be necessary for graft coverage in some cases. Occasionally, in situ repair may not be advisable due to the quality of the arteries or the surrounding tissue. Ligation of the native arteries in the groin and an extraanatomic bypass, such as an obturator bypass, may be preferable.¹¹¹ Ligation of the common femoral artery without reconstruction is utilized as a last resort and is less likely to threaten the limb if the femoral bifurcation remains intact.¹¹²

Conversely, infected common femoral artery pseudoaneurysms secondary to intravenous drug abuse should be preferentially managed with aggressive arterial and soft tissue debridement and ligation of all of the involved arteries. Immune suppression due to malnutrition and human immune deficiency virus infections, delayed presentation, and patient recidivism make arterial reconstruction hazardous in this setting. Reddy showed that ligation of the common, superficial, and profunda femoral arteries is associated with a 33% major amputation rate.¹¹³ Rates of major amputation are very low in other series, with some authors reporting zero amputations in their series.^{114,115} Claudication is almost universal, however with debridement and femoral artery ligations.²⁷ Some authors recommend limiting revascularization attempts to patients with absent pedal Doppler signals after ligation of the femoral vessels, whereas others recommend amputation for all subjects with infected pseudoaneurysms due to intravenous drug abuse.¹¹⁶

Table 88-1 Complications Associated with Different Methods of Aortic Reconstruction after Aortic Graft Excision, Based on Selected Publications

	Method of Aortic Reconstruction	30-Day and Long-Term Mortality	Primary Patency	Limb Salvage	Reinfection	Pros (+)/Cons (-)
7	Extraanatomic bypass with aortic ligation ⁷⁷⁻⁸¹	30-day: 11–28% 1-year: 14–58%	73–75%	73–93%	3.25%	(+): Reduced morbidity (staging) (-): decreased patency, stump blowout (0–22%), increased amputation and reinfection rates
9	In situ autogenous vein ^{2,103}	30-day: 8–10% 5-year: 40–48%	81–91%	93–100%	0–5%	(+): resistant to reinfection, excellent long-term durability and limb salvage, cost-effective (-): time-consuming, fasciotomy in up to 25%
10	In situ allograft ⁹⁴⁻⁹⁸	30-day: 3–20% 1-year: 7–26%	81–97%	97–100%	0–4%	(+): resistant to reinfection, excellent long-term durability and limb salvage (-): rupture and pseudoaneurysmal degeneration, cost, persistent infection
8	In situ rifampin-soaked graft ^{99,101,102}	30-day: 8% 1-year: 16–21%	89–100%	100%	4–12%	(+): excellent patency, convenience (-): higher reinfection rates
	In situ silver-impregnated graft ^{105,106}	30-day: 7–21% 1-year: 15–26%	92–100%	96–100%	4–16%	(+): excellent patency, convenience (-): highest reinfection rates

Arterial Infections in Other Sites

Carotid patch infection is a rare, but dreaded occurrence. Management entails removal of the patch, wide debridement, and primary closure of the artery versus vein patch closure. Interposition grafting with autogenous vein is often necessary after the artery is debrided adequately. Occasionally ligation of a bleeding, infected artery is necessary as a life-saving intervention.¹⁸ In a series of carotid patch infections, the stroke rate after debridement and reconstruction was 8.1% and increased to 14% when carotid ligation was necessary.¹⁸ Endografting is an acceptable option to control hemorrhage and permit stabilization and evaluation for definitive surgery.¹¹⁷

Case reports and small case series of infected pseudoaneurysms of the superior mesenteric, celiac, and splenic arteries have been reported.^{118,119} Treatment is individualized by the patient's comorbidities and anatomy. Infected visceral artery aneurysms are prone to rapid growth and rupture.^{118,119} Arteriography is often helpful to delineate the anatomic relationship of the aneurysms to nearby branch vessels and to define the quality of the collateral circulation. Excision, debridement, and arterial reconstruction with autogenous conduit remain the gold standard for infected pseudoaneurysms of main arterial trunks. Resection and arterial ligation may be an option in some cases, depending on the anatomic location due the abundant collateral circulation between the mesenteric arteries and branches.¹²⁰ Coil embolization and long-term antibiotic therapy should be reserved for surgically inaccessible aneurysms, such as intrahepatic mycotic pseudoaneurysms, since coils may become infected.^{121,122}

ANTIBIOTIC THERAPY

Unfortunately, there are no guidelines directing the type, dose, duration, or route of administration of antibiotics in treating arterial infections. This reflects the wide spectrum of causal organisms that are found in arterial graft infections, with approximately one-third of subjects having polymicrobial infections. Moreover, physician preference and patient tolerance of antibiotic regimens vary considerably. In addition, culture-directed therapy is not always possible since nearly 40% of patients have negative cultures, presumably due to preoperative broad-spectrum antibiotic therapy.⁴ Finally, the consequences of a reinfection are dire, so there is a tendency among physicians to overprescribe antibiotics.

Initial broad-spectrum antibiotics should include agents with activity against gram-positive bacilli, gram-negative rods, and anaerobes, as these are the most prevalent organisms in graft infections. Currently our preferred combination therapy is vancomycin, piperacillin/tazobactam, and metronidazole. Blood cultures and graft and tissue cultures should be obtained to direct therapy.

Recommendations for the duration of antibiotics vary widely, ranging from 2 to 8 weeks after graft excision. If a graft or stent is not fully excised, indefinite antibiotic therapy should be considered. Fungal infections are particularly difficult to eradicate and may require the use of micafungin (FK463) due to the increasing incidence of resistance to fluconazole and its related molecules.¹²³

PREVENTION OF SECONDARY ARTERIAL INFECTIONS

Meticulous surgical technique is critical to minimizing arterial graft infections. Judging from the microbial flora associated with graft infections, intraoperative contamination and surgical site infections are the most likely sources of contaminations that result in arterial graft infections. Adherence to all perioperative guidelines for reducing surgical site infections is important, but the use of prophylactic systemic antibiotics appears to be critically important. A recent meta-analysis and systematic review performed by Stewart concluded that prophylactic systemic antibiotics decreased the risk of wound and early graft infection for peripheral arterial reconstruction.¹²⁴ No benefit was seen in continuing antibiotics for greater than 24 hours, prophylactic rifampin-bonding to the grafts, suction groin wound drainage, or preoperative bathing with or without antiseptic agents.

CONCLUSIONS

Primary and secondary arterial infections constitute a myriad of some of the most technically, intellectually, and emotionally challenging cases that vascular surgeons may encounter in clinical practice. For aortic arterial infections, there is no consensus regarding the optimal method of in situ reconstruction. Autogenous vein reconstruction may be the most resistant to recurrent infection and most cost effective, but requires an additional, lengthy procedure for vein harvest. Reconstruction with either antibiotic- or silver-impregnated grafts may also be a reasonable alternative, but appears to have a higher rate of reinfection compared to the alternatives. Cryopreserved allografts have improved since their initial development, but are still hampered by a minority of hemorrhagic complications and pseudoaneurysmal degeneration. Moreover, cryopreserved allografts are considerably more expensive than the other alternatives. Extraanatomic bypass remains a viable alternative for patients unable to undergo a more extensive operation. Endovascular stent grafts are excellent tools to stabilize patients with hemorrhagic complications of arterial infections prior to definitive surgery. Arterial infections in other locations utilize the same principles of wide excision and debridement, arterial reconstruction, and appropriate antibiotic coverage whenever technically feasible.

Cerebrovascular Disease

Martyn Knowles and Carlos H. Timaran

Key Points

- 1 Worldwide stroke has become the second leading cause of death
 - 2 Atherosclerotic occlusive disease of the extracranial carotid artery accounts for a major cause of ischemic stroke
 - 3 Duplex ultrasonography is of great use in the identification of cerebrovascular disease
 - 4 Risk factor modification is imperative in patients with atherosclerotic cerebrovascular disease
 - 5 Surgical treatment for occlusive carotid artery disease is preferred over medical management for symptomatic disease and severe asymptomatic disease
 - 6 Carotid artery stenting continues to be evaluated for efficacy
 - 7 The diagnosis of vertebrobasilar insufficiency is often difficult due to subtle symptoms shared by many organ systems
 - 8 Endovascular management of vertebral artery disease has not been sufficiently investigated for efficacy
 - 9 Open repair of brachiocephalic disease should be based on patient comorbidities, and high-risk patients should undergo extra-anatomic revascularization
-

INTRODUCTION

Stroke continues to be a common cause of death and disability. The morbidity caused by a stroke can be debilitating, worse than that of a myocardial infarction (MI). Stroke can cause permanent disability that includes aphasia, paralysis, blindness, numbness, or weakness. If transient, <24 hours, it is termed a transient ischemic attack (TIA) and manifests similarly. Long-term sequelae from stroke can have long-lasting financial and social burdens on a patient, family, and the healthcare system in general.

Atherosclerotic plaque at the bifurcation of the carotid artery extending into the internal carotid artery continues to be a common cause of CVA, accounting for approximately 40% to 60% of all ischemic strokes. Since the introduction of the carotid endarterectomy (CEA) in 1954, operative treatment of carotid artery occlusive lesions has been shown in multiple randomized trials to decrease the risk of subsequent ipsilateral ischemic strokes. More recently, endovascular carotid artery stenting (CAS) techniques have seen a surge in popularity; however, controversy still exists regarding the appropriate use of endovascular intervention, and the evaluation of surgical, endovascular, and medical management of carotid occlusive disease continues to be investigated.

Vertebral artery occlusive disease typically occurs at the origin of the vertebral arteries – due to atherosclerosis – and can cause posterior circulation symptoms, such as diplopia, drop attacks, and vertigo. The diagnosis of vertebrobasilar disease is usually more difficult than carotid occlusive disease as the symptoms are often vague and can be confused easily with other diagnoses. Treatment has traditionally been open surgical repair; however, endovascular repair is feasible although outcomes have not been evaluated extensively.

Brachiocephalic occlusive disease is most often caused by atherosclerosis and involves the origin of the great vessels. Symptoms can include stroke, TIA, and arm fatigue and weakness. Diagnosis often requires imaging and a keen physical examination. Treatment involves either extra-anatomic or transthoracic surgical repair or more recently the introduction of endovascular management with angioplasty and stenting.

This chapter provides a comprehensive review of epidemiology, pathophysiology, diagnosis, treatment, and controversy in the management of carotid artery occlusive disease, as well as vertebral artery and brachiocephalic occlusive disease.

CAROTID ARTERY OCCLUSIVE DISEASE

Epidemiology

1 Worldwide, stroke is the second most common cause of mortality and third of disability.¹ The incidence appears to be decreasing in the United States; however, is increasing in low-income countries.^{2,3} In the United States, the annual incidence of a new or recurrent stroke is 795,000, of which 610,000 are first-ever strokes.⁴ There appear to be a higher number of strokes in the Southeast United States as compared to other regions. Men have a higher risk of stroke at younger ages, but women have a higher risk over the age of 75 years.⁴ The risk of stroke appears to be affected by race, with whites having a lower incidence than blacks and Hispanics in the United States.^{5,6} The risk of first-ever strokes in blacks is twice that in whites.⁷ Recently, stroke has been decreased from the third leading cause of death in the United States to the fourth. This decrease is related to a decrease in the incidence of strokes over the last few decades, up to a 40% decrease since the 1980s.^{8,9} This decrease in mortality has been fueled by improvements in acute stroke care over the years. The incidence of TIA is approximately 2.3% and has a higher risk of subsequent stroke. TIAs can herald a stroke 15% of the time, usually within the first 90 days.⁷ The risk factors for stroke include age over 55, male sex, hypertension, family history, atrial fibrillation, smoking, hypercholesterolemia, diabetes, obesity, renal insufficiency, and alcohol. Overall, five factors cause a significant number of strokes: hypertension, smoking, obesity, diet, and physical inactivity.¹⁰

PATHOGENESIS OF STROKE

The etiology of CVA in the United States is most commonly related to ischemia (87%), intracerebral hemorrhage (10%), and subarachnoid hemorrhage (3%).⁴ Ischemia can be broken down into thrombosis, embolism, and hypoperfusion. Thrombosis refers to in situ obstruction of an artery, typically from atherosclerosis, dissection, or fibromuscular dysplasia (FMD). A stroke occurs from reduced flow distal to the thrombosis, and can be either large or small vessel. Large vessels include the extracranial carotid and proximal intracranial arteries. Small vessel disease is branch vessels from the intracranial vessels. Embolism refers to debris from a source, such as the heart or arterial segment, that becomes free and flows downstream until lodging in a small vessel. Hypoperfusion refers to a more global circulatory problem. Often there is a combination of etiologies that leads to a stroke such as a pre-existing lesion that becomes a source of emboli.

2 Atherosclerosis is the most common cause of disease in the extra- and intracranial carotid arteries. This etiology remains a major preventative cause of ischemic stroke. The incidence of carotid artery disease is 3.8% to 10.5% in men and 2.7% to 5.5% in women.^{11,12} Although, a definitive cause of stroke is often not identified, large vessel cervical disease is a major cause in about 15% of cases (Fig. 89-1). Stroke from carotid vessel etiology also has the highest rate of recurrence at 30 days.¹³

The carotid bifurcation is an area of low flow and shear stress, due to a separation of flow between the high-resistance external carotid artery and the low-resistance internal carotid artery (Fig. 89-2). Plaque usually forms in this area due to the shear stress, and forms on the walls opposite from the flow divider. As per typical atherosclerosis formation, the inciting event is intimal injury. There is then platelet deposition, smooth muscle proliferation, fibroplasia, and loss of the luminal diameter. As the lumen diameter gets smaller, the flow velocities and turbulence increase which can lead to hypoperfusion or atheroembolization (Fig. 89-3). Furthermore, a large number of carotid plaques have a necrotic core of lipid rich debris and cholesterol. There is a fibrous cap that separates this from the lumen, which is typically a thin rim of cellular components and extracellular matrix. This thin cap can rupture and cause plaque disruption which can have severe clinical consequences. Hemorrhage within the plaque can also occur and is an important risk factor for rupture of the cap. Additionally, dense plaque inflammation with macrophage infiltration is strongly associated with cap rupture. Conversely, the presence of a thick plaque is associated with a more stable plaque.

Figure 89-1. Stroke due to carotid bifurcation occlusive disease is usually caused by atheroemboli arising from the internal carotid artery, which provides the majority of blood flow to the cerebral hemisphere. With increasing degrees of stenosis in the carotid artery, flow becomes more turbulent, and the risk of atheroembolization escalates.

Figure 89-2. A: The carotid bifurcation is an area of low flow velocity and low shear stress. As the blood circulates through the carotid bifurcation, there is separation of flow into the low-resistance internal carotid artery and the high-resistance external carotid artery. **B:** The carotid atherosclerotic plaque typically forms in the outer wall opposite to the flow divider due in part to the effect of the low shear stress region, which also creates a transient reversal of flow during the cardiac cycle.

Figure 89-3. Duplex ultrasonography showing a carotid plaque with narrowing of the vessel lumen that can either embolize or cause low flow causing hypoperfusion. B-mode imaging shows a heterogeneous plaque with severe narrowing.

CLINICAL MANIFESTATIONS OF STROKE

Symptomatic carotid artery disease is classically thought of as a corresponding TIA, stroke, or amaurosis fugax. A TIA is a neurologic event that manifests stroke-like symptoms for <24 hours. These are considered a precursor of a more serious event and a large number will progress to a stroke. Symptoms correspond with a focal defect that can be related to carotid artery atherosclerosis. These symptoms typically include the anterior or middle cerebral artery circulations. Motor symptoms can include hemiparesis contralateral to the affected hemisphere. Sensory deficits can also occur in a similar fashion, such as numbness or paresthesia. Aphasia, dysphagia, or dysarthria can also occur. Amaurosis fugax is the temporary monocular blindness from cholesterol embolization to the retinal artery via the ophthalmic artery. Dizziness, syncope, vertigo, seizures, bowel or bladder incontinence, or migraines are not typically related to carotid disease and other causes must be sought. Once the symptoms progress past 24 hours, the TIA has become a full stroke. The full severity of a stroke can often take weeks to manifest as the penumbra either recovers or does not. Global ischemia is generally uncommon with carotid artery disease.

DIAGNOSTIC EVALUATION

3 Carotid artery duplex ultrasonography (DUS) is the primary diagnostic tool for the evaluation of carotid artery disease. Although the role in screening is controversial, those with concerning symptoms should undergo DUS. The benefits of DUS include excellent sensitivity for the diagnosis of occlusive carotid artery disease, but also the avoidance of radiation and the rapid availability and ease of evaluation. The decision for carotid intervention is often taken solely on the information provided by the DUS. A complete examination includes evaluation of the common, external, and internal carotid arteries, as well as the vertebral arteries, and often the subclavian arteries. The peak systolic velocity (PSV), end-diastolic velocity (EDV), and the ratio of the common carotid artery to internal carotid artery (CCA/ICA) are used to determine the severity of stenosis (Fig. 89-4). Although labs differ in their ranges, patients are typically classified into: normal, 1% to 49%, 50% to 69%, 70% to 99% or occluded (Table 89-1). Additionally, the DUS can provide important information regarding the plaque morphology. The identification of high-risk echolucent plaques can aid the practitioner in estimating the risk of neurologic symptoms. The diagnostic accuracy of DUS does, however, depend on having a skilled sonographer. Magnetic resonance angiography (MRA) and computerized tomographic angiography (CTA) are becoming more popular for diagnosis with improvements in the technology. These imaging modalities can provide important information regarding the aortic arch, tortuosity, brachiocephalic disease, carotid bifurcation location, and intracerebral collateral circulation. They can, however, overestimate the amount of stenosis and often require correlation with DUS. Angiography remains the gold standard for diagnosis; however, the procedure itself carries approximately 1% risk of neurologic complications (Fig. 89-5). Transcranial Doppler (TCD) can provide information related to the significance of a stenosis and how it alters intracerebral hemodynamics.

Figure 89-4. A: Color power Doppler shows a severe stenosis at the origin of the internal carotid artery. B: The peak systolic velocity is 497 cm/s, correlating to a >70% stenosis.

Table 89-1 Duplex Ultrasound Criteria for Carotid Artery Stenosis

Degree of Stenosis (%)	ICA PSV (cm/s)	ICA EDV (cm/s)	ICA/CCA Ratio	Carotid Plaque (%)
Normal	<125	<40	<2.0	None
<50	<125	<40	<2.0	<50
50–69	125–230	40–100	2.0–4.0	>50
70–99	>230	>100	>4.0	>70
Occlusion	Undetectable	Undetectable	Not applicable	100

ICA, internal carotid artery; PSV, peak systolic velocity; EDV, end-diastolic velocity; CCA, common carotid artery.

TREATMENT OF CAROTID ARTERY OCCLUSIVE DISEASE

Patients with carotid artery occlusive disease are placed into two main categories: asymptomatic or symptomatic. A recent (<6 months) TIA, stroke, and amaurosis fugax are considered symptoms of occlusive carotid disease. These patients have the highest risk of recurrence of symptoms or possible ipsilateral stroke. In patients who have a TIA, 15% will go on to a CVA, 10% within 90 days.⁷ Several studies have examined the risk reduction of stroke with medical and surgical management.

SYMPTOMATIC

Patients with symptomatic lesions are at the highest risk of ipsilateral stroke, and the degree of stenosis corresponds with the risk. Validated in multiple trials – most prominently in the North American Symptomatic Carotid Endarterectomy Trial (NASCET) study – the degree of stenosis was correlated with Stroke risk. A stenosis <50% was unlikely to cause neurologic manifestations. In patients with >50% stenosis, those treated with medical therapy were more likely to progress to ipsilateral stroke than those that underwent surgical management. This benefit to surgical intervention was highest in the 70% to 99% stenosis range. In the NASCET study, symptomatic patients were assigned to medical therapy or endarterectomy with symptomatic disease and a stenosis >50%. After 2 years, there was a significant reduction in ipsilateral stroke in those who underwent a CEA ([50% to 69% stenosis: 22.2% in medical patients and 16.7% in surgical patients over 5 years] and [70% to 99% stenosis: 26% in medical patients and 9% in surgical patients over a 2-year period]).¹⁴ The European Carotid Surgery Trial (ECST) showed similar findings for severe stenosis, however, no benefit was found to surgery over medical management with mild stenosis.¹⁵ Medical therapy has advanced since the NASCET trial with the introduction of improved antiplatelet medications such as clopidogrel, and HMG-CoA reductase inhibitors. In the NASCET trial, aspirin was the medical therapy that surgery was compared against. Aspirin is an important medication in secondary stroke prevention. It can be used alone or in combination with dipyridamole or clopidogrel. Most neurologists recommend aspirin and clopidogrel in symptomatic patients for prevention of stroke until surgical intervention is performed. Statins lower stroke risk by 30% by plaque stabilization and are important for the reduction of stroke.¹⁶

Figure 89-5. A carotid angiogram with digital subtraction angiography reveals a patch repair after prior endarterectomy.

Timing of intervention after stroke continues to be debated. Traditionally, surgeons waited >6 weeks prior to intervention but there is a chance of recurrent stroke which is highest in the short term. Performing the surgery too soon can also have devastating consequences such as hemorrhagic conversion of an ischemic lesion. In patients that have returned to baseline from their symptoms, the current thought is to undergo surgery somewhere between around 2 days and 2 weeks after the event.¹⁷ If the patient doesn't return to normal or has a dense lesion on imaging, it is best to wait a few weeks. Crescendo TIA and evolving stroke are different entities and although the risk of stroke with intervention is slightly higher, urgent revascularization is warranted to prevent a large stroke.

ASYMPTOMATIC

4 Treatment for patients with symptomatic disease is well established in the literature, however, the treatment of asymptomatic carotid disease is not so clear-cut. Detection of a carotid stenosis is typically based on a DUS finding or evidence of a carotid bruit. The rate of neurologic symptoms with an asymptomatic bruit was estimated to be 4% per year.¹⁸ One of the first and most important trials regarding asymptomatic patients was the Asymptomatic Carotid Atherosclerosis Study (ACAS) trial. In ACS, asymptomatic patients with $>60\%$ stenosis were randomly assigned to either medical management or CEA. After 5 years, best medical therapy was found to be inferior to surgery in regard to ipsilateral CVA (11% for medical management vs. 5.1% for CEA over 5 years). Therefore with endarterectomy, there was a risk reduction in stroke of 53%.¹⁹ In Europe, the Asymptomatic Carotid Surgery Trial (ACST) showed similar results, with a benefit in patients undergoing surgery over medical management in patients with $\geq 60\%$ stenosis.²⁰ The biggest benefit comes from severe stenosis and it is generally accepted that surgical intervention be pursued for stenosis $\geq 80\%$, with 60% to 79% remaining controversial. Antiplatelet therapy is also recommended in the form of aspirin for asymptomatic stenosis.²¹ There does not appear to be a benefit to the addition of clopidogrel.²² Best medical management with risk factor modification is mandatory for all patients with severe carotid stenosis, whether symptomatic or asymptomatic. Currently, several clinical trials are comparing carotid intervention versus best medical management for the treatment of asymptomatic carotid stenosis.

CAROTID ENDARTERECTOMY VERSUS CAROTID STENTING

The choice for intervention in symptomatic ($>50\%$ stenosis) and asymptomatic ($>80\%$ stenosis) patients is currently widely accepted. The next decision is to which treatment modality should be undertaken. CEA traces back to the 1950s and is considered the gold standard for the surgical treatment of occlusive carotid artery stenosis. Since the Food and Drug Administration (FDA) approved CAS in 2004, there was a proliferation of the technology and use for the treatment of symptomatic and

asymptomatic carotid disease. High-risk patients from an anatomic or medical reason, as well as elderly patients were thought to benefit from CAS over CEA. The Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy (SAPPHIRE) trial examined CAS versus CEA for high-risk patients (medical comorbidities and anatomical features), and CAS was associated with a lower risk of major events at 1 year, with a greater advantage in asymptomatic patients.²³ The Endarterectomy Versus Angioplasty in Patients with Symptomatic Severe Carotid Stenosis Trial (EVA-3S) trial was a European trial for symptomatic patients with >60% stenosis that was stopped prematurely due to higher 30-day stroke risk with CAS. However, embolic protection device was optional and its use was associated with similar results to CEA.²⁴ The Stent-Supported Percutaneous Angioplasty of the Carotid Artery versus Endarterectomy trial (SPACE) trial examined patients with ≥70% symptomatic stenosis failing to prove noninferiority of CAS to CEA.³⁸ Most recently, the Carotid Revascularization Endarterectomy versus Stenting Trial (CREST) examined CAS versus CEA in standard-risk patients for both symptomatic and asymptomatic patients. Overall, there was no difference between CAS and CEA long-term, but this was likely due to a higher rate of MI with CEA, and a higher rate of periprocedural CVA with CAS. Despite the similar rate of complications overall, stroke-related complications portended a worse long-term survival.²⁵ Currently, the Centers for Medicare and Medicaid Services (CMS) limits reimbursement for CAS to high-risk symptomatic patients with carotid stenosis >70%.

5 6 Despite some uncertainty regarding CAS versus CEA, there are some subpopulations that do better than others with a particular treatment option. Contrary to initial belief regarding advanced age as a benefit for carotid stenting, age ≥68 was associated with a significantly higher risk of stroke and death for carotid stenting.^{25,26} Symptomatic patients undergoing CAS appear to have a higher risk of stroke or death if performed in <7 days after the symptomatic event.²⁷ There are no sufficient data to support CAS for asymptomatic patients outside high risk for CEA by anatomical factors (stoma, previous neck radiation, contralateral vocal cord paralysis, or high lesion) or severe medical comorbidities (coronary or pulmonary disease) (Table 89-2). Furthermore, patients with significant anatomical factors that put them at risk for CAS should undergo CEA (Table 89-3). Currently, ongoing clinical trials seek to determine more understanding of the patients that will benefit best from each therapy as well as the assessment of new stent designs, such as mesh-covered stents.

Table 89-2 Criteria for High-Risk Carotid Endarterectomy

Clinical Criteria
Unstable angina
NYHA class III or IV CHF
LVEF <35%
MI <6 weeks
Severe pulmonary disease
Severe renal impairment
Contralateral recurrent laryngeal nerve injury
Anatomical Criteria
High lesion above C2
Tandem lesions >70%
CEA restenosis
Cervical immobility
Prior neck irradiation
Tracheostomy
Previous neck surgery

NYHA, New York Heart Association; CHF, congestive heart failure; LVEF, left ventricular ejection fraction; MI, myocardial infarction; CEA, carotid endarterectomy.

CAROTID ENDARTERECTOMY

Technique

There are many decisions a surgeon has to consider for a CEA. First, there is the choice of anesthetic: local, regional, or general. Depending on the choice of anesthetic, there is a choice of cerebral monitoring. If the patient has the procedure under local anesthesia, their ability to respond to

commands dictates the adequacy of collateral flow during clamping. If the patient is under general anesthesia, there is the choice of electroencephalogram (EEG), TCD, stump pressure measurement, or somatosensory evoked potentials (SSEPs) that guide the use of a shunt for cerebral protection. EEG is the most widely used technique of cerebral monitoring. It requires the addition of 8 to 16 leads and monitors brain activity. The use of a shunt is based on a positive test, which is a drop of fast background activity of 50%. EEG, however, is likely overly sensitive, overestimating the number of people that require a shunt.^{28,29} TCD works in a similar manner, evaluating the middle cerebral artery (MCA) for changes in flow with clamping. Measuring a stump pressure requires clamping the common and external carotid artery while maintaining the internal carotid artery open and using a transducer to check the back pressure. A minimum mean pressure of 40 mm Hg has been most widely adopted for the threshold for shunting. Stump pressure measurement does, however, have a small risk of embolization. Others opt for routine shunting, allowing a consistent endarterectomy technique without anxiety. Shunting completely relieves intracerebral ischemia, but requires a safe technique with shunt placement above the superior aspect of the plaque. Routine shunting has been met with excellent results.^{30,31}

Table 89-3 Contraindications to Carotid Artery Stenting

Carotid Artery Stenting Contraindications
Fresh thrombus
Severe kinking of ICA
Unstable plaque
Brachiocephalic vessel tortuosity
Brachiocephalic vessel severe stenosis or occlusion
Circumferential calcification
Poor arterial access
Acute aortic arch angle
Significant aortic arch plaque or thrombus

Correct patient positioning is paramount for a successful endarterectomy, especially for a high lesion. The patient’s neck is slightly hyperextended and turned away, with a roll under the shoulder to open the neck ([Fig. 89-6](#)). A longitudinal incision is made along the anterior border of the sternocleidomastoid muscle (SCM). The use of ultrasound intraoperatively can help guide the surgeon to perform a limited incision over the bifurcation. The platysma is divided. Care must be taken to avoid the anterior jugular vein and carefully divide any venous tributaries. By retracting the SCM laterally the internal jugular vein is identified in the carotid sheath. The facial vein is an important landmark for identification of the bifurcation and is divided, however, frequently the hypoglossal nerve can traverse at this site and care must be taken to avoid it. Often the superior belly of the omohyoid muscle is divided for exposure. Inferior and medial to the internal jugular vein is the common carotid artery which is carefully exposed. Care must be taken to avoid injuring the vagus nerve that is typically posterior to the artery, but can travel anteriorly in some cases. After the common carotid artery is dissected out, the external carotid and superior thyroid arteries are controlled. Often, dissection at the carotid bifurcation can cause reactive bradycardia because of stimulation of the carotid body. This can be improved with administration of 1% lidocaine directly into the carotid body. Care must be taken in dissecting out the internal carotid artery to avoid excessive manipulation to prevent embolization and avoid the more common location of the hypoglossal nerve that traverses the proximal artery. For high lesions, extension of the incision posteriorly in a periauricular fashion and division of the posterior belly of the digastric muscle can aid in distal exposure. If a lesion is felt to be very high, preoperative nasotracheal intubation and mandibular subluxation with temporary fixation can assist in exposure of the distal ICA.

Figure 89-6. The patient's neck is slightly hyperextended and turned to the contralateral side. An incision is made along the anterior border of the sternocleidomastoid centered over the carotid bifurcation.

Once all vessels are controlled, intravenous heparin is administered (100 units/kg) prior to clamping (Fig. 89-7). As discussed previously, the choice of cerebral monitoring or routine shunting dictates how the surgeon proceeds. Typically, the internal carotid artery is clamped first to avoid embolization after ensuring the clamp site is in a normal segment of artery distal to the palpable plaque. The external and common carotid arteries are then clamped. A longitudinal arteriotomy is created from the distal common carotid artery into the internal carotid artery past the plaque. Often the ansa cervicalis limits exposure as it traverses the carotid artery, which requires its ligation once it is indeed identified as the ansa cervicalis. If necessary, a shunt can be placed from the common carotid artery to the internal carotid artery to maintain antegrade flow (Fig. 89-8). An endarterectomy can be performed to remove the plaque. Typically, a layer is teased out in the media, and the entire plaque is removed after either cutting the plaque from the proximal and distal artery or carefully pulling free trying to avoid a flap. The plaque extending into the external carotid artery is most easily dealt with by way of an eversion technique. The entire endarterectomized surface must be examined to remove flaps or debris. This is of most importance at the distal aspect in the internal carotid artery. If needed, tacking sutures with 7-0 prolene can be used to keep down a concerning endpoint to avoid a flap once flow resumes (Fig. 89-9).

At this point, closure of the arteriotomy is accomplished. Primary repair is not typically recommended due to improved short- and long-term outcomes with patch closure, and CMS uses patch closure as a quality metric during endarterectomy.³² The choices of patch include synthetic material, such as Dacron or polytetrafluoroethylene, a biologic material, such as bovine pericardium, or an autogenous vein (Fig. 89-10). Prior to closure, the shunt is removed and careful sequential flushing of each of the vessels is performed to remove air or debris. Additionally, after closure, the internal carotid artery clamp remains on for a few seconds to allow flushing through the external carotid artery to ensure any remaining debris of thrombus does not proceed into the cerebral circulation. The heparin is typically reversed with protamine sulfate. Once hemostasis is accomplished, closure is performed by approximating the sternocleidomastoid back, closing the platysma and skin. A full neurologic examination is performed prior to extubation or exit from the operating room if performed under local anesthesia.

An eversion endarterectomy is another technique for CEA and has the benefit of not requiring prosthetic material for a patch. In the eversion technique, exposure of the vessels is similar to the standard CEA. However, with the eversion technique, the internal carotid artery is transected at the bulb. The edges of the vessel are peeled back in a plane removing the plaque as it proceeds distally. A downside of the eversion technique is the inability to easily use distal tacking sutures. Closure is primarily accomplished at the bifurcation and doesn't compromise the internal carotid artery lumen.

Figure 89-7. A: During carotid endarterectomy, vascular clamps are applied to the common carotid, external carotid, and internal carotid arteries. Carotid plaque is elevated from the carotid lumen. B: Carotid plaque is removed and the arteriotomy is closed either primarily or with a patch angioplasty.

COMPLETION STUDIES

Avoidance of a perioperative stroke is the primary objective during and after the endarterectomy. To minimize that risk, typically caused by a technical error such as a flap, thromboembolism, or carotid artery thrombosis, completion studies should be considered. At the completion of arterial closure, continuous wave Doppler analysis can be used to check the patency of the vessels by identifying normal Doppler flow or an area of stenosis. This is unlikely to pick up a small intimal flap or subtle stenosis. DUS is an excellent modality for examination of blood flow waveforms and B-mode imaging to identify small flaps or intimal defects. Angiography is considered the “gold standard” with contrast either injected directly into the common carotid artery or via a transfemoral approach. However, these studies have shown mixed results in the identification of defects, or can be overly sensitive and pick up defects that might not cause problems while repair increases the morbidity and mortality.^{33,34}

Figure 89-8. A temporary carotid shunt is inserted from the common carotid artery (*long arrow*) to the internal carotid artery (*short arrow*) during carotid endarterectomy to provide continuous antegrade cerebral blood flow.

Figure 89-9. The distal transition line (left side of the figure) in the internal carotid artery where the plaque had been removed must be examined carefully and should be smooth. Tacking sutures (*arrows*) are placed when an intimal flap remains in this transition to ensure no obstruction to flow.

Figure 89-10. A: An autologous or synthetic patch can be used to close the carotid arteriotomy incision, which maintains the luminal patency. B: A completion closure of carotid endarterectomy incision using a synthetic patch.

Complications

The majority of patients tolerate the endarterectomy well and are discharged home after 24 hours. Complications can range from mild to life threatening. Postoperative blood pressure control often requires pharmacologic assistance due to carotid sinus manipulation during the procedure, but rarely persists after 24 hours. An acute ipsilateral stroke is the most dreaded complication after a CEA, especially if performed for asymptomatic disease. Cerebral ischemia can occur due to hypoperfusion or embolization during the procedure. Hypoperfusion is related to the collateral flow through the contralateral carotid artery and posterior circulation, and often relies on the status of the circle of Willis. Embolization can occur from shunt placement, the clamp site, thrombus formed during the procedure, or inadequate flushing prior to arteriotomy closure. Less frequently, the carotid artery can occlude causing a stroke. This can be related to an intimal flap, platelet adhesion from the patch, dissection, or anastomotic stricture. The importance of neurologic evaluation prior to leaving the operative suite is the quick identification of a problem, and usually requires immediate reexploration. Alternatively, if there was a normal postoperative duplex, angiography can be performed for the identification of the etiology of the stroke. The perioperative risk after CEA differs depending on the indication for the intervention. In symptomatic patients, the 30-day risk of stroke is 3.2% to 5.4%, MI 1.8% to 2.6%, and death around 1.1%.^{14,24,25,38} For asymptomatic patients, the 30-day risk of stroke is 1.4% to 5.4%, MI is 2%, and death is 1.1%.^{14,24,25,38} In CREST, the 30-day stroke and death rate after CEA was 3.2% in symptomatic and 1.2% in asymptomatic patients. Additionally, when identifying symptomatic patients treated by vascular surgeons, the 30-day risk of stroke and death was 1.3%, which increased to 3.9% when combined with MI. Overall with endarterectomy, CREST showed a periprocedural risk of death at 0.3%, CVA of 2.3%, and MI of 2.3%.²⁵

Cardiac complications are common after CEA, and are a major cause of perioperative death.^{35,36} This risk is due to the high number of patients with concomitant coronary artery disease, upward of 50% of patients. Postoperative bleeding can cause a significant hematoma that can cause respiratory

compromise. An expanding hematoma should be evacuated emergently and the bleeding source identified. Cranial nerve injuries are a common complication, however, the incidence varies greatly with a range between 1% and 30%, more common experience showing an incidence of 0.5% to 4.7%.^{25,37} Cranial nerve injuries are shown in [Table 89-4](#). Cerebral hyperperfusion is an uncommon complication after CEA. The cause of hyperperfusion is disordered autoregulation of arteriolar cerebral blood flow after return of flow after a tight stenosis. Symptoms start with a headache and progress to seizures and intracerebral hemorrhage with a high mortality rate. Severe hypertension is a risk factor and requires urgent lowering of the blood pressure and anticonvulsant therapy. Contralateral severe internal carotid artery stenosis is another important risk factor for the development of cerebral hyperperfusion syndrome. Restenosis can occur after CEA. If occurring within 2 years, it is likely related to intimal hyperplasia and can improve. After 2 years, it is likely caused by atherosclerosis. Patch infection and pseudoaneurysm formation are also other complications following CEA.

Carotid Stenting

Technique

CAS requires careful patient identification and examination of adequate preoperative imaging for procedural success. Prior to intervention, axial imaging is highly recommended. This is most generally an MRA or CTA with thin cuts. This should include imaging from the aortic arch all the way to beyond the circle of Willis. Examination of the aortic arch will identify those with anatomy that would make brachiocephalic vessel cannulation and the tracking of wires and catheters difficult. With excessive manipulation, or not identifying arch pathology, a stroke could be possible. The angle of the aortic arch, brachiocephalic ostial disease, tortuosity of brachiocephalic vessels, arch thrombus, or calcification must all be identified for safe carotid stenting. Furthermore, there are specific lesion characteristics that can make stenting more difficult or risky, such as, hypoechoic plaque, ulceration, lesion length, circumferential calcification, or thrombus. A careful physical examination must be performed to identify femoral and iliac artery anatomy that would make arterial access difficult. Although the transfemoral approach is the most common, there are a variety of other approaches that are possible, including transcervical or transradial.

Table 89-4 Cranial Nerve Injuries Associated with Carotid Endarterectomy

Cranial Nerve Injuries	
Vagus	Unilateral: rarely serious; Bilateral: vocal cord paralysis, tracheostomy
Recurrent laryngeal	Unilateral: rarely serious; Bilateral: vocal cord paralysis, tracheostomy
Superior laryngeal	Voice fatiguability, voice modulation difficulty
Hypoglossal	Unilateral: rarely serious; Bilateral: articulation, swallowing difficulty, tracheostomy
Glossopharyngeal	Dysphagia, aspiration
Marginal mandibular	Appearance of drooping ipsilateral lip
Spinal accessory	Shoulder droop, scapular winging

Prior to the carotid stenting procedure, the patient should be on dual antiplatelet therapy, typically aspirin 325 mg for at least a week prior and have received around 450 mg of clopidogrel. The procedure is either performed in an angiography suite or hybrid operating room. The patient requires arterial line placement for blood pressure control and should stay awake during the procedure for frequent neurologic checks. The patient is placed in the supine position and the groins are prepped. Retrograde femoral access is gained and the patient is heparinized (100 units/kg). Thoracic angiogram is rarely required because previous CTA or MRA can clearly define arch anatomy. Selected catheterization is then performed. The anatomy dictates the combination of wire and catheter that will work in a particular situation. Angiography after proximal carotid artery cannulation should be performed to evaluate the stenosis for location and severity, contralateral circulation, vertebrobasilar circulation, and intracerebral circulation. These can all influence the approach to the procedure. Balloon occlusion, for instance, may not be a good option for embolic protection if preoperative imaging and

angiography reveal an incomplete circle of Willis and inadequate collateral flow.

Once the decision is made to proceed with carotid stenting, selective catheterization of the ipsilateral external carotid artery is accomplished, as long as the lesion does not involve its origin, and the catheter advanced. Great care must be taken to avoid inadvertently manipulating the lesion and risk embolization distally. Once the catheter is in the external carotid artery, a long stiff 0.035-in-wire is exchanged and navigated through the arch. Significant tortuosity can often require subsequent maneuvers for success, such as breath holds or the use of special guiding sheath and selective catheter systems that can be advanced over each other seamlessly in difficult anatomy. At this point a 90-cm 6-Fr sheath is advanced into the proximal common carotid artery, again insuring that the sheath is not advanced past the beginning of the plaque. The stiff wire is removed and angiography is again performed for mapping purposes, assisting in cannulation of the internal carotid artery ([Fig. 89-11](#)). Most practitioners use embolic protection devices (EPDs) to reduce the risk of CVA during the procedure during wire manipulation, balloon angioplasty, and stent placement. There is a choice of distal filters, distal balloon occlusion, and flow stasis or reversal ([Fig. 89-12](#)). Flow stasis or reversal creates a situation where there is no antegrade flow in the internal carotid artery so embolization is unlikely to occur. After completion of any case, suction can be performed to remove any free floating debris. The benefit of flow reversal is the avoidance of having to cross the lesion unprotected. Filter protection requires wire cannulation past the lesion and placement of a filter in the distal internal carotid artery for embolic protection. The filter is removed at the completion of the case. Significant vasospasm in the distal internal carotid artery may occur when a filter is used.

The EPD is carefully advanced over a 0.014-in wire into the distal internal carotid artery and deployed. All remaining parts of the procedure occur over the EPD wire via a rapid exchange platform. Predilatation of the lesion is typically accomplished with a 4- to 5-mm balloon, but should be used sparingly as it can increase the risk of stroke. There are a variety of stents available, generally either open or closed cell. This is in regard to the structure of the stent. The stents are self-expanding and their flexibility is determined by the number of connections between the cells of the stent. The more connection, the stiffer the stent (closed cell). Decisions regarding the type of stent depend on the lesion characteristics, tortuosity, and symptomatic status. Most practitioners prefer closed-cell stents for use in symptomatic patients to lessen embolization or extrusion of the plaque through the stent ([Fig. 89-13](#)).

Figure 89-11. Carotid angiography shows a high-grade stenosis with “string sign” in the internal carotid artery with underfilling of the distal artery.

The size of the stent typically depends on the size of the internal and common carotid artery and comes in straight and tapered configurations. Once the stent is deployed, often postdilatation is necessary ([Fig. 89-14](#)). Care must be taken with balloon dilatation near the bulb as severe bradycardia can occur secondary to stimulation of the glossopharyngeal nerve. Atropine should be immediately

available and good communication with nursing and anesthesia is important. The EPD is removed and completion angiography is performed. The sheath is then removed and the puncture site closed with a closure device or manual compression. As heparinization is not typically reversed, it is common to use a closure device, which allows early mobilization and hemodynamic stability. Throughout the procedure the patient is assessed from a neurologic standpoint. Postprocedure the patient is monitored similar to a CEA. The patient continues clopidogrel for 1 month and aspirin for life.

Complications

The most important and serious complication after carotid stenting is neurologic events. As the vast majority of patients are awake, MI is much less frequent. The risk of MI after carotid stenting is lower than CEA: 0.4 to 1.1 versus 0.6 to 2.3.^{24,25,38} The EPD can cause distal ICA vasospasm, dissection, or occlusion if full of debris. A full filter should be removed slowly, a dissection treated with stenting, and nitroglycerin injection used for severe vasospasm. Acute thrombosis of the stent can cause a profound neurologic defect and usually requires immediate explantation and endarterectomy. An embolus identified on angiography can be managed with neurorescue. Options include aspiration thrombectomy, catheter-directed thrombolysis, or snare removal. Intracerebral hemorrhage is a rare complication. Other complications include access site complications, such as bleeding and pseudoaneurysms.

Nonatherosclerotic Disease of the Carotid Artery

Carotid Coiling and Kinking. The internal carotid artery typically takes a straight path into the skull. At times there can be excessive elongation and tortuosity that makes a coil ([Fig. 89-15](#)). This can occur congenitally and is seen in children, or it occurs in adults with elongation over time due to elasticity and excessive angulation. This results in a C or S shape of the vessel. A kink is elongation with angulation that exceeds 90 degrees. Kinks can cause cerebral hypoperfusion, and rarely can embolize. Head position with rotation and either flexion or extension can exacerbate the symptoms. Treatment is indicated for ipsilateral cerebral symptoms, and other nonspecific symptoms, such as dizziness, syncope if no other causes are found. Options for treatment include transposition to a more proximal area in the common carotid artery, or segmental resection.

Fibromuscular Dysplasia

FMD is a nonatherosclerotic disorder that can affect a variety of vascular beds within the body. Most commonly found in the renal and iliac arteries, FMD is also found in the carotid and vertebral artery

systems with an incidence of 0.42%.³⁹ Carotid FMD is associated with cerebral aneurysms. The exact etiology of FMD is unknown. There are four types of FMD, most commonly the medial fibroplasia, with the classic appearance of a “string of beads.” This angiographic appearance is seen in the majority of cases and is caused by segmental encroachment of the arterial lumen and poststenotic dilatation and can be a nidus for hypoperfusion and embolization. The internal carotid artery is usually involved and the lesion avoids the bifurcation. FMD can however be associated with vertebral and renal FMD, cerebral aneurysms, and carotid aneurysms/dissection. Up to 50% of patients with internal carotid FMD have associated cerebral aneurysms.⁴⁰

Duplex ultrasound can be used for diagnosis; however, can miss the typical appearance or identify elevated velocities. CTA has replaced a need for angiography, although angiography does remain the “gold standard.” CTA or MRA is useful for the identification of intracerebral aneurysms.

The natural history of FMD is not well established. If FMD is associated with symptoms, repair is indicated. Asymptomatic patients can be treated with antiplatelet agents, however, do progress over time.⁴⁰ With concomitant atherosclerosis, identification of the cause of symptoms must be identified. Surgical treatment focuses on breaking the webs associated with FMD. This can be performed via open or endovascular means. In open repair, dilators are introduced through a common carotid arteriotomy with progressively increasing sizes. Although the technique allows for backbleeding, the risk of stroke remains from debris caused by rupturing the webs.

Figure 89-15. Duplex ultrasonography with color shows an extremely tortuous internal carotid artery.

CAROTID ARTERY DISSECTION

Dissection of the carotid artery can either be spontaneous or secondary to a precipitating event, such as trauma. Although carotid artery dissections account for a small number of overall strokes, they account for up to 20% of strokes in younger patients.⁴¹ Spontaneous dissection is common in the carotid and vertebral arteries due to their mobility and proximity to bony structures. Chiropractic manipulation is a major cause of spontaneous dissection. There is usually no atherosclerosis present in patients who develop carotid dissection. The classic triad in carotid dissection is neck or head pain, Horner syndrome, and cerebral ischemia; however, it is rare to have all three. Headache is the most common symptom, typically ipsilateral frontotemporal in location. Patients can also develop TIA, CVA, nausea, amaurosis fugax, and cranial nerve palsies. CTA, MRA, and DUS are all utilized for diagnosis, and angiography remains the gold standard. The treatment options for carotid artery dissection typically begin with anticoagulation or antiplatelet therapy. There are no head-to-head trials comparing the two; however, most patients are treated for a minimum of 3 months with intravenous heparin and transition to oral anticoagulation. The indications for surgical treatment include the inability to anticoagulate, worsening symptoms on anticoagulation, aneurysm formation, or severe neurologic symptoms with severe flow limitation. Options for surgical repair include surgical bypass, patch angioplasty, or carotid ligation (thought to be safe if the stump pressure is >70 mm Hg).⁴² Results of endovascular stenting are promising for the treatment of carotid dissection.

CAROTID ARTERY ANEURYSMS

Carotid artery aneurysms are uncommon at about 1%; however, pseudoaneurysms after endarterectomy

can occur more frequently. True aneurysms are most frequently caused by degeneration or atherosclerosis and are typically at the carotid bifurcation or proximal internal carotid artery (Fig. 89-16). Other causes include penetrating or blunt trauma, and dissection. A pulsatile mass is the most frequent presenting symptom. Other patients can suffer from hemispheric neurologic symptoms, such as a TIA or stroke, or cranial nerve dysfunction, such as Horner syndrome. Rupture is exceedingly rare. Given the rarity of this disease entity, little is known regarding conservative management, and most undergo surgical repair with bypass, and less frequently patch repair. A balloon occlusion test is helpful prior to surgical intervention for large or distal aneurysms, and provides the possibility to bail out with ligation of the carotid artery.

Figure 89-16. Duplex ultrasonography shows an extracranial carotid artery aneurysm in the proximal internal carotid artery.

CAROTID BODY TUMORS

Carotid body tumors arise from neural crest tissue from the third branchial arch. These masses usually arise in the adventitial tissue at the carotid bifurcation. There are multiple neural crest tumors, including carotid body tumors, paragangliomas, and glomus tumors. Paragangliomas can secrete catecholamines and have systemic effects much like pheochromocytomas. These tumors are very rare. They occur more often in situations of hypoxemia, like altitude, smoking, and chronic obstructive pulmonary disease (COPD). Malignancy is rare, approximately 5%, and can metastasize to the lymph nodes, liver, and skin. There is a hereditary pattern in carotid body tumors and can account for as much as 35% of all cases. These masses arise at the carotid bifurcation and can envelope the internal and external carotid arteries and the surrounding cranial nerves. DUS is useful for diagnosis with a characteristic splaying of the internal and external carotid arteries. Needle biopsy is not recommended for diagnosis as they are extremely hypervascular with blood flow arising from the external carotid artery. Treatment involves resection, and large masses can benefit from preoperative embolization. Surgical treatment involves similar exposure to a CEA and is carefully peeled off the underlying arteries; however, can be injured and require bypass (Fig. 89-17). There is a high risk of cranial nerve injuries with repair at approximately 10%.⁴³

CAROTID TRAUMA

The extracranial carotid artery can be affected by blunt or penetrating trauma. Injury can be intimal disruption, dissection, thrombosis, pseudoaneurysm formation, or transection. Penetrating cervical trauma with concern for major arterial injury should undergo evaluation and treatment based on location. Historically, zone 2 injuries undergo surgical evaluation due to the ease of surgical exposure. Zone 1 and 3 injuries require workup for identification of an injury. Zone 1 injuries will require a median sternotomy for control, whereas zone 3 will require maneuvers similar to high exposure for an endarterectomy or the use of endovascular coil embolization or coverage with a stent graft. CTA is the modality of choice for diagnosis in carotid injury. However, angiography remains the “gold standard” for diagnosis. Medical management of a dissection includes either antiplatelet or anticoagulation. However, if a dissection degenerates into a pseudoaneurysm, intervention is required by either open or endovascular stent placement. Acute carotid thrombosis is treated with anticoagulation if the patient is asymptomatic. Revascularization is required for patients with cerebral ischemia.

Figure 89-17. Carotid body tumor located at the bifurcation of the internal and external carotid artery.

VERTEBROBASILAR DISEASE

Anatomy

The vertebral arteries are paired arteries that arise from the subclavian arteries. Rarely, variants can occur, the most common being a direct origin of the left vertebral artery arising from the aortic arch. The vertebral artery is composed of four segments: V1 is the origin of the vessel up to the C6 transverse process, V2 is the segment that runs within the vertebral foramina to the level of C2, V3 is the next segment above C2 before it enters the base of the skull, and V4 is the intracranial portion of the artery before it joins with the contralateral side forming the basilar artery.

Clinical Findings

7 The vertebral and basilar arteries make up the posterior circulation to the brain and pathology can lead to posterior circulation ischemia. This system provides blood flow to the brainstem, cerebellum, and posterior lobes of the brain. About one-fourth of ischemic strokes involve the posterior circulation.⁴⁴ Vertebrobasilar ischemia is a commonly misdiagnosed clinical syndrome, mostly due to the more subtle and broad symptoms associated with them in comparison to the anterior circulation. The importance of correct diagnosis cannot be stressed enough as the mortality rate for posterior circulation strokes is 20% to 30% higher than for anterior circulation strokes.⁴⁵ Symptoms related to the vertebrobasilar system are bilateral in nature. Symptoms include diplopia, vertigo, drop attacks, dysphagia, ataxia, disequilibrium, and paresthesias.

Pathogenesis

The cause of vertebral artery disease can either be embolic or from low flow, with low flow causes predominating. Embolic phenomena are difficult to recognize and are more commonly from the heart, aorta, and brachiocephalic vessels. Proximal atherosclerotic lesions can embolize, and are more likely to lead to irreversible ischemia and infarction, and thus are more debilitating. Additionally, multiple foci of ischemia are common. Overall, approximately 20% of posterior circulation strokes arise from an arterial source.⁴⁴

Low flow accounts for around 30% of posterior circulation strokes.⁴⁴ Low flow is more likely to cause transient symptoms and is due to inadequate collateral circulation. Anything that alters the flow to the posterior circulation can elicit these symptoms (end organ hypoperfusion), most likely rapid postural changes, or alteration of the cardiac output. As opposed to embolic phenomena, low flow is unlikely to cause infarction. Unlike embolism, manifestation of symptoms from hypoperfusion requires either bilateral disease or unilateral disease with poor collateral circulation from the contralateral vertebral artery and/or circle of Willis.

Differential Diagnosis

Atherosclerosis is the main cause of vertebrobasilar pathology. There are other etiologies that include dissection, trauma, FMD, aneurysms, and Takayasu disease. Given the subtle symptomatology, there are a variety of other organ systems that can mimic symptoms. Syncope or presyncope is sometimes

confused with vertebrobasilar symptoms. This can be caused by a multitude of causes such as cardiac arrhythmias, vasovagal events, neurologic, psychiatric, or unexplained. Patients often describe visual changes that can be mistaken for diplopia, such as myopia or presbyopia, cataracts, floaters, amaurosis fugax, and a variety of other visual complaints. Disequilibrium and vertigo can be caused by many etiologies, and can be confused for postural instability, hearing loss, and nystagmus. In addition, a variety of metabolic disorders can mimic vertebral artery disease.

Diagnostic Evaluation

DUS is extremely useful in the identification of vertebral artery disease, however, is more difficult than the examination of the extracranial carotid arteries. This is due to the location and depth of the vessel, and evaluation of the vessel between C2 and C6 is difficult. Direct visualization of the cervical vertebral artery can identify proximal stenosis and reversal of flow. Examination of the bilateral pulses and blood pressure can further help identify significant differences between the arms, which would suggest proximal disease.

CTA and MRA are useful imaging modalities and allow careful examination of the vessels throughout their course, identify disease, and elucidate collateral circulation. MRI also allows precise identification of embolism and the diagnosis of a stroke. Angiography is considered the “gold standard.” This allows careful examination of the vertebral arteries including the origin, however, multiple views are often needed for correct diagnosis. Information about collateral circulation is also shown via contralateral and anterior circulation.

Distribution of Disease

The V1 segment of the vertebral artery is the most common area of involvement with 92% of patients having atherosclerotic disease at the origin of the vertebral artery.⁴⁶ Extrinsic compression via osteophytes is common in the V2 segment, as is trauma, aneurysms, and dissections. V3 lesions are most likely caused by trauma and dissections due to the mobility of this section of the artery. V4 is infrequently the site of vertebral artery disease, but may be affected by trauma or dissection.

Open Surgical Treatment

Open reconstruction of vertebral artery disease depends on the location of disease. For a V1 lesion, transposition of the vessel to the common carotid artery is preferred. Another option is a bypass from either the common carotid or subclavian artery to the vertebral artery distal to the disease with either graft or saphenous vein. A less commonly performed procedure is the subclavian artery endarterectomy. For lesions or bleeding in the V2 location, typically proximal and distal ligation suffices. A bypass to the V3 segment can be performed if it is felt that there is not enough collateral circulation. Options for the V3 segment include bypass using saphenous vein to the C1–2 segment. The external carotid artery can also be swung over and act as a conduit, after all branches are taken. Reconstruction for the V4 segment is technically demanding, and requires exposure of the suboccipital segment via resection of the C1 transverse process.

Results are limited to case series and mainly reports from a single surgeon, with a low risk of stroke and death <1%.⁴⁷ Other complications include nerve injury (vagus and recurrent laryngeal nerve), Horner syndrome, and lymphatic leak. The risk of reconstruction of the distal vertebral artery has a higher risk of stroke and death rate (3%) than proximal lesions.⁴⁸ Symptoms are alleviated in 71% to 80% of patients, with 10-year patency of 82% to 91%.^{48,49}

ENDOVASCULAR TREATMENT

8 Endovascular management of vertebral artery disease has gained favor due to the relative ease of repair in contrast to the open repair. The risks that plague any cerebrovascular endovascular intervention hold true for vertebral artery disease with the risk of embolization, stroke, thrombosis, dissection, and restenosis. Distal protection can be used to decrease the risk of embolization by way of an EPD. Angioplasty alone is fraught with high rates of restenosis and the need for reintervention at close to 50%.⁵⁰ Additionally, the stroke rate appears to be quite high at 6.4% at 30 days.⁵¹ There are small randomized trials comparing intervention with medical management.

Brachiocephalic Disease

Anatomy

The aorta arises as it emerges from the aortic valve. The ascending and transverse arch are separated into the aortic root (aortic valve, three sinuses, and the coronary arteries), tubular portion, and transverse arch. Most commonly, the aortic arch has three main trunks. These three trunks arise in order from proximal to distal; innominate artery, left common carotid artery, and left subclavian artery. There are a few variations that exist relating to these main branch vessels. Most commonly, the innominate and left common carotid artery come off the arch in one common ostia, the “bovine arch.” This variant is found in 8% of whites and up to 25% of blacks.⁵² Another common variant is the presence of an aortic origin for the left vertebral artery found in 6% of the population that arises between the left common carotid artery and the left subclavian artery. An aberrant right subclavian artery occurs when the origin for the right subclavian artery comes off the aorta distal to the left subclavian artery and courses posteriorly behind the arch, and occurs approximately 0.5% to 1% of the time.^{53–55}

CLINICAL FINDINGS

Atherosclerosis is the most common disease that affects the brachiocephalic vessels. The clinical scenario depends on the location of disease and how many vessels are involved. Up to 40% of the time multiple vessels are involved.⁵⁶ The clinical picture depends on multiple factors. Disease of the subclavian artery typically causes embolization, arm claudication or easy fatigability. Occlusive disease involving the subclavian artery typically manifests as pain and fatigue with continued arm use. With more severe cases, rest pain and tissue loss can occur. Involvement of the origin of the subclavian artery can cause subclavian steal, vertebrobasilar insufficiency, or myocardial ischemia if proximal to a functioning LIMA coronary bypass (subclavian coronary steal). Rarely, hemiparesis or aphasia can occur. Involvement of the innominate artery can lead to a stroke, TIA, or similar symptoms to subclavian artery involvement. Common carotid disease can lead to TIA or stroke. Multivessel disease can present as a combination of all these symptoms.

DIFFERENTIAL DIAGNOSIS

Atherosclerosis is the most common cause of brachiocephalic occlusive disease. The typical picture in atherosclerosis is an ostial lesion. Vasculitides, such as Takayasu and Giant cell arteritis, can affect the brachiocephalic arteries (Fig. 89-18). There are infectious processes that can affect the brachiocephalic vessels. Syphilis and tuberculosis are the most common infectious causes of brachiocephalic disease, albeit rare, and can lead to aneurysm degeneration of the brachiocephalic artery, and most commonly the subclavian arteries. Penetrating and blunt trauma can affect the brachiocephalic vessels. Thoracic outlet obstruction, often related to cervical ribs, can cause subclavian artery aneurysms. These aneurysms can lead to embolism and distal ischemia.

Figure 89-18. Duplex ultrasonography showing thickening along the common carotid artery and narrowing of the lumen, consistent with Takayasu arteritis.

DIAGNOSTIC EVALUATION

A comprehensive physical examination is prudent for the identification of brachiocephalic disease. Absence of pulses in the extremities can signify proximal disease in either the subclavian or innominate arteries. Blood pressure measurement can identify subtle differences between the arms, with a significant finding being greater than 20 mm Hg between sides. Auscultation can identify carotid and subclavian bruits.

DUS is typically the first imaging modality used for the identification of disease. DUS can evaluate the carotid arteries with direct visualization of the majority of the extracranial system. It is often difficult to visualize the proximal vessels as they arise from the aortic arch; however, indirect findings can suggest disease. A decrease in the waveform amplitude and slope (tardus-parvus waveform) can signify significant proximal disease. Additionally, reversal of flow in a vertebral artery can signify innominate or proximal subclavian artery disease and a steal syndrome.

Other modalities include CTA and MRA (Fig. 89-19). These modalities provide excellent imaging of the aorta and brachiocephalic branches. The images, especially when used with 3D reconstructions, avoid the use of angiography for diagnosis and allow careful planning for surgical treatment. Thorough examination of the arterial flow to the brain and collateral circulation is prudent prior to surgical intervention. Gated CT in coordination with the patient's electrocardiogram allows careful identification of the mobile ascending aorta and arch and decreases motion artifact. Angiography is the “gold standard,” although it has associated risks such as stroke, embolization, and arterial injury. Another option is transesophageal echocardiogram which can be used to rule out proximal extension of a dissection, or ascending, arch, and descending aortic pathology.

Figure 89-19. Magnetic resonance angiography (MRA) with brachiocephalic vessel disease. There is a critical stenosis of the innominate artery and left common carotid artery. There is also a severe proximal left subclavian artery stenosis.

INDICATIONS FOR REPAIR

In general, repair is indicated for symptomatic disease. Asymptomatic disease should be monitored for progression of disease and medical management of risk factors. A stroke or TIA should prompt repair due to the continued risk of embolization or low flow state. A low threshold for repair should be given to those with an internal mammary bypass and proximal subclavian artery disease. Upper extremity tissue loss, rest pain, and significant exertional pain are indications for repair.

OPEN SURGICAL TREATMENT

There are two general categories for open surgical repair of brachiocephalic disease. Those are transthoracic and extra-anatomic revascularization. Transthoracic repair requires a median sternotomy and direct revascularization. This modality is ideal for low-risk patients and those with multilevel

disease. In the case of the treatment of Takayasu arteritis, debranching off the ascending aortic arch to the healthy involved vessels is best to avoid diseased arterial segments. Options for repair include aortic endarterectomy, bypass grafts, and arch replacement with bypass. Results are excellent with 10-year patency around 90%.^{57,58} Complications include mortality and stroke rates of 3% to 8% and MI rates of 1.5% to 3%.⁵⁷⁻⁵⁹

9 Based on the patient's comorbidities and surgical risk, extra-anatomic revascularization carries the benefit of the avoidance of the risk associated with a median sternotomy. In recent years with the introduction of endovascular techniques for repair of aortic and brachiocephalic pathologies, extra-anatomic procedures are used in conjunction for hybrid repair in high-risk patients. Options for repair include a carotid-carotid bypass, axilloaxillary bypass, carotid-subclavian bypass and carotid-subclavian transposition. The transposition avoids the use of a conduit; however, is contraindicated in those with a previous left mammary bypass graft due to intolerance of proximal clamping. Results are excellent with 10-year patency greater than 80%.⁵⁶ Mortality rates are lower than those that underwent transthoracic repair at less than 1%, with slightly lower stroke and MI rates.^{56,60}

Figure 89-20. **A:** Critical stenosis of the innominate artery with distal wire access for endovascular management. **B:** Placement of a balloon-expandable stent for treatment of the innominate artery stenosis. **C:** Final angiographic run showing complete resolution of stenosis.

ENDOVASCULAR TREATMENT

As with carotid stenting, the option for endovascular treatment of brachiocephalic disease depends of the aortic anatomy, anatomical variants, baseline renal function, arch type, lesion characteristics, and proximity to branch vessels (Fig. 89-20).

Options for repair include angioplasty and stenting. This does require intraprocedural anticoagulation and antiplatelet therapy after repair. Results of repair do not appear to compare to open repair, however, there is a paucity of data regarding long-term results. One-year patency appears to be around 90% and 5-year patency drops to 77% to 89%.⁶¹⁻⁶³ Given these results, surveillance is required and follow-up procedures for assisted patency are required.

Care must be given to avoid embolization to the vertebral arteries when intervening on the subclavian arteries or the internal carotid arteries when intervening on the innominate or common carotid arteries. This is usually accomplished with a filter being placed distal to the target area of revascularization with a 0.014-in-based system. Separate access or use of the 0.014 wire with a rapid exchange system allows protection during intervention. However, the risk of embolization is low and risks associated with filter placement should be weighed.

Chapter 90

Upper Extremity Arterial Disease

Heron E. Rodriguez

Key Points

- 1 Presentation includes arm claudication, distal embolism, finger necrosis, and vasomotor changes described as Raynaud phenomenon.
 - 2 Given the multiple potential etiologies of upper extremity ischemia, a thorough occupational and social history is of crucial importance.
 - 3 Unilateral hand ischemia points toward an isolated anatomic lesion whereas bilateral hand ischemia is more often related to systemic diseases.
 - 4 A variety of noninvasive tests are available for the initial investigation of arm ischemia and detailed, bilateral arterial imaging is mandatory for treatment planning.
 - 5 Although endovascular revascularization is an excellent option for many causes of upper extremity ischemia, open surgical revascularization should be used for some of the diseases causing arm ischemia (i.e., thoracic outlet syndrome, hypothenar hammer syndrome, etc.)
-

INTRODUCTION

1 Compared to arterial occlusive lesions in the lower extremity, occlusive disease of the arteries of the upper extremity is often better tolerated and severe symptoms of ischemia are less frequent in the arms than in the legs. This not only can be attributed to the presence of an extensive collateral network, but also to the very different physiologic requirements of the upper extremities when compared to the legs. Another striking difference between arterial disease of the arms compared to that of the legs resides in its etiology. Whereas in the lower extremities, atherosclerosis is responsible for the overwhelming majority of cases of critical limb ischemia, in addition to atherosclerosis, a variety of anatomic, occupational, and iatrogenic etiologies are responsible for occlusive disease of the arms.

PRESENTATION

Patients suffering from arterial insufficiency affecting the upper extremities can present with a variety of symptoms. Arm claudication (pain during exercise) is rare and often points to a lesion in the proximal vasculature (innominate, subclavian, or axillary arteries). More commonly, patients present with skin changes affecting the hand or fingers. Splinter hemorrhages of the bed of the nail, livedo reticularis, cyanosis of segments of the fingers, and gangrene are signs of embolism or ischemia affecting the arteries of the hand (Fig. 90-1).¹ The term Raynaud phenomenon indicates an episodic series of skin changes affecting the fingers or the hand that are triggered by changes in temperature and sometimes even emotions. The classic description includes the sequential appearance of pallor, then cyanosis, then erythema. These correspond to initial vasospasm (causing pallor), desaturation of hemoglobin (causing cyanosis), and finally compensatory vasodilation, also known as reactive hyperemia (causing erythema).

Raynaud phenomenon (also called secondary Raynaud syndrome) can be the manifestation of occlusive disease or, more commonly, associated with autoimmune conditions (scleroderma, Sjögren syndrome, rheumatoid arthritis, lupus).¹ In contrast, the term *Raynaud disease* (or primary Raynaud syndrome) is used to describe a condition of unknown etiology that occurs in patients without occlusive lesions or autoimmune disease and who experience vasomotor symptoms in both arms, and sometimes even the legs, for longer than 2 years.²

ETIOLOGY

2 A myriad of conditions can cause upper extremity occlusive disease (Table 90-1). Atherosclerosis typically affects the origins of the supra-aortic trunks. Ostial lesions at the origin of the subclavian artery are most common. The innominate artery and distal arteries can also be affected. Involvement of multiple segments of the upper extremity circulation is possible and is often asymptomatic even in the presence of total occlusion. Patients with renal failure typically have normal proximal vessels with severe disease in the blood vessels of the forearm and hand (Fig. 90-2). In this patient population, hand ischemia tends to occur at a younger age and is frequently associated with calciphylaxis.³

Inflammatory conditions like Takayasu arteritis, giant cell arteritis or temporal arteritis can also affect the proximal portion of the great vessels.⁴ Takayasu arteritis is a nonspecific inflammatory disease that has a predilection for young women. This so-called “pulseless disease” typically occurs in women in the second or third decades of life who present with symptoms of ischemia in the arms or the cerebrovascular territory. An initial acute inflammatory phase of the disease leads to a late chronic phase where long segments of stenosis appear in the vessels (Fig. 90-3). These lesions have a low embolic potential but typically result in ischemic symptoms due to low flow. In contrast, giant cell arteritis involves the more distal segments of the subclavian arteries and affects older people. The typical pattern of disease is that of areas of normal luminal diameter alternated with dilated or stenotic lesions. The most common symptoms are headaches and visual changes related to involvement of the cerebral vascular arteries. Buerger disease is an obliterative disease that typically affects medium and small caliber arteries. The *sine qua non* for Buerger disease is tobacco use in a young patient. It affects the lower extremities more commonly than the upper limbs and occurs more frequently in males than females.

Figure 90-1. Manifestations of upper extremity ischemia. Splinter hemorrhages in the nails arising from a proximal embolic source (A). Gangrene affecting the tip of the third finger (B). Advanced, severe gangrene in the radial artery distribution secondary to complications related to an arterial line (C).

Ergotamine-induced vasospasm can create ischemia of the hands and the feet. Historically, several epidemics occurred in Europe during the Middle Ages caused by the ingestion of rye contaminated by alkaloid-producing fungi. After a miraculous cure that was believed to have occurred thanks to the relics of Saint Anthony the Great, the Hospital Brothers of St. Anthony's order was founded and the term “St. Anthony's Fire” became popular. Today, most cases of ergotism are due to antimigraine drugs or

recreational substance abuse.⁵

Connective tissue disorders are a common cause of upper extremity ischemia. Lesions typically affect the distal vasculature and are more common in scleroderma, rheumatoid arthritis, CREST syndrome, mixed connective tissue disorder, and lupus. Raynaud phenomenon is often the manifestation in early stages whereas digital gangrene occurs in late stages of the disease.

Peet et al. first coined the term thoracic outlet syndrome (TOS) in 1956 to encompass a group of signs and symptoms related to compression of the brachial plexus, subclavian artery, or subclavian vein as they pass from the thorax into the axilla. Only in 1% of all cases of TOS, the artery, is the structure compressed. Although TOS is often asymptomatic, patients may present with a range of signs and symptoms, from fatigue or pain in the affected arm upon exertion and Raynaud phenomenon to critical ischemia of the upper extremity because of emboli arising from the chronically injured artery or from a mural thrombus in a poststenotic aneurysm sac. The artery is compressed as it passes through the thorax into the axilla through the narrow gap formed by the clavicle superiorly, the first rib inferiorly and the subclaveous muscle anteriorly and superiorly, as well as the scalene muscles posteriorly (Fig. 90-4). Bony anomalies, such as cervical rib or an abnormal first thoracic rib, are sometimes present. Aneurysms can also form because of repetitive trauma in branches of the subclavian artery. These aneurysms can be the source of emboli that manifest as ischemic lesions in the hands.⁶ Pectoralis minor syndrome is a distinct condition caused by compression of the subclavian artery by the pectoralis minor as it travels cephalad to insert in the coracoid process (Fig. 90-4).

Ischemia caused by abnormalities in the axillary, brachial, radial, and ulnar arteries is often the result of iatrogenic etiologies. One of the most common causes of ischemia seen in our practice is due to hemodialysis access. Hand ischemia due to steal phenomenon is common and ischemia as a result of intra-arterial catheters also occurs frequently.

Occupational injuries to the arteries of the hand result in thenar or hypothenar hammer syndrome. The ulnar artery is vulnerable to injury at the hypothenar eminence, just distal to the wrist where the ulnar artery passes through Guyon canal bound by the pisiform and hamate bones. Here, the ulnar artery is cushioned only by skin, subcutaneous tissue, and the thin palmaris brevis muscle. Repetitive use of the palm of the hand as a “hammer” compresses the unprotected ulnar artery against the nearby hook of the hamate bone. Both aneurysm formation and occlusive disease can occur (Fig. 90-5).⁷

HISTORY AND PHYSICAL EXAMINATION

3 Given the frequent association of upper extremity ischemia with systemic and occupational disorders, a thorough medical and social history is mandatory. Interrogation should include inquiring about tobacco and drug use. Antimigraine medications, HIV antivirals, and most commonly recreational drugs, like cocaine and other alkaloids, can cause ergotism. Occupational history is of particular importance when evaluating upper extremity vascular issues. TOS occurs in athletes who are required to perform repetitive overhead shoulder motion (swimmers, baseball pitchers, weight lifters, etc.). Repetitive trauma to the palmar eminences (thenar and hypothenar) is typically observed in manual laborers (machinists, carpenters, and construction workers) but has also been described in athletes, musicians, and even computer workers who use their hands repetitively causing injury to the palms.

ETIOLOGY

Table 90-1 Conditions and Risks for Upper Extremity Ischemia

Occupational injury	Frisbee	Polycythemia vera
Vibration syndrome	Karate	Behçet syndrome
Pneumatic tools	Handball	Antiphospholipid syndrome
Chainsaws	Pharmacologic history	Thoracic outlet syndrome
Grinders	Ergot poisoning	Congenital arterial wall defects
Electrical burns	Beta blockers	Pseudoxanthoma elasticum
Hypothenar hammer syndrome	Drug abuse, cocaine use	Ehlers–Danlos syndrome
Mechanical work or auto repair	Cytotoxic drugs	Fibromuscular dysplasia
Lathe operation	Dopamine overdose	Iatrogenic injury
Carpentry	Medical conditions	Arterial blood gas and pressure monitoring
Electrical work	Atherosclerosis	Cardiac catheterization
Occupational acroosteolysis – polyvinylchloride exposure	Arteritis	Arteriography
Athletic activities	Collagen disease	Frostbite
Thoracic outlet compression	Scleroderma	Renal transplantation and related problems
Baseball pitching	Rheumatic arteritis	Azotemic arteriopathy
Kayaking	Systemic lupus erythematosus	Hemodialysis shunts
Weight lifting	Dermatomyositis	Radiation
Rowing	Allergic necrotizing arteritis	Breast carcinoma
Butterfly swimming	Takayasu disease	Hodgkin disease
Golfing	Giant cell arteritis	Aneurysms of the upper extremity
Hand ischemia	Blood dyscrasias	
Baseball catching	Cold agglutinins	
	Cryoglobulins	

Figure 90-2. Selective left-hand angiogram in a patient with chronic renal insufficiency. There is severe, diffuse disease affecting a heavily calcified ulnar artery (*arrow*). In addition, there is lack of contrast opacification in several of the digital arteries.

Figure 90-3. Aortogram in the right oblique projection of a patient with Takayasu arteritis. Long-segment right common carotid

stenosis (*small arrows*) leading into a normal appearing carotid bifurcation. Segmental occlusion of the right subclavian artery (*block arrow*) just distal to the origin of the right vertebral. There is distal reconstitution via a large collateral. There is also an aneurysm (*star*) of a previous bypass in the left subclavian artery.

Figure 90-4. Compressive zones of the thoracic outlet. The subclavian structures can be compressed at the costoclavicular space, the scalene triangle, or distally at the border of the pectoralis minor muscle.

The presence of atherosclerotic disease in the heart or other vascular beds should also be investigated. History of connective tissue disorders or their symptoms (dysphagia, arthritis, telangiectasia, and other skin abnormalities) cannot be obviated during the evaluation of upper extremity ischemia. Changes in the appearance of the skin of the hands suggestive of Raynaud's should be explicitly investigated.

Figure 90-5. Ulnar artery aneurysm resulting from repetitive trauma in a construction worker.

It is necessary to obtain clear documentation of any prior intervention in the arm (hemodialysis access, biopsies, brachial or axillary access for cardiac catheterizations) or episodes of trauma (clavicular or rib fractures, humeral, shoulder, or elbow injuries) (Fig. 90-6).

A complete physical examination needs to include a systemic evaluation looking for signs of atherosclerotic, inflammatory, or autoimmune disease. A meticulous inspection, auscultation, and palpation of both sides of the neck, periclavicular areas, shoulders, and the entire arms and hands is

done in the resting, neutral position, and also while abducting the arm. A bruit or a thrill in the periclavicular area would suggest the presence of stenosis or poststenotic dilation arising from TOS and a prominent pulse should point to an aneurysm in the subclavian artery. Comparison between the two upper extremities is of crucial importance since bilaterality often points to a systemic disorder. A careful hand examination includes inspecting for splinter hemorrhages under the beds of the nails, skin evidence of embolism or gangrene, changes in the color of the skin related to vasospasm and signs of trauma in the hand. Careful palpation of the radial, ulnar, snuffbox, and even digital pulses is done. Digital pressure is then applied to the ulnar and radial arteries in the wrist. After the patient opens and closes his or her hand, pressure is removed from one of the wrist arteries and inspection of the color of the hand and palpation of the distal pulses is repeated (Allen test). The test is normal if the entire hand recovers its color and capillary refill. If a portion of the hand fails to normalize, suspicion arises that the palmar vascular collateral circulation (palmar arch) is incomplete. Finally, blood pressure measurements in both arms are obtained and compared (brachio-brachial index).

Figure 90-6. Old clavicular fracture treated with a metallic prosthesis. Notice the luminal abnormality in the subclavian artery as it crosses the clavicle. This lesion was caused by periosteal scarring and caused distal embolism in the hand.

LABORATORY AND NONINVASIVE TESTING

4 A series of serologic tests is typically obtained when autoimmune disease is suspected (Table 90-2). A variety of tests are available from the blood flow laboratory to aid in the management of upper extremity occlusive disease.⁸ All patients should be subjected to segmental arterial pressure measurement and waveform analysis, at the minimum. In the upper extremities, this test usually includes photoplethysmography (PPG) of the digital vessels. The absence of triphasic flow and the presence of “blunted” PPG tracing in the affected arteries and digits, respectively, helps to localize obstructive lesions. If intermittent occlusion is suspected due to TOS, noninvasive testing can be performed along with the use of provocative maneuvers (Fig. 90-7). In patients with symptoms suggestive of vasomotor disorders (cold intolerance, color skin changes, etc.) the cold challenge test is used. In our lab, we immerse the hands in iced water and measure the digital temperatures every 5 minutes. A normal response should normalize the digital temperature within 1°C of preimmersion measurements. Patients with cold intolerance fail to restore digital temperature in 20 minutes. Several variations of this test exist.⁹

DIAGNOSIS

Table 90-2 Lab Tests for Systemic Causes for Hand Ischemia

Erythrocyte sedimentation rate
Rheumatoid factor
Antinuclear antibody
Immunoglobulin electrophoresis
Cryoglobulins
Cold agglutinins
VDRL (Venereal Disease Research Laboratory) test
Complement (C3, C4)
Anticardiolipin antibody
Blood cell counts

Figure 90-7. Noninvasive blood flow study in a major league baseball pitcher showing loss of normal signals during proactive maneuvers.

Figure 90-8. Focused magnetic resonance angiogram of the hands.

A more sophisticated version of the Adson test can also be obtained in most blood flow facilities by

adding the analysis of waveforms obtained before and after ulnar and/or radial artery occlusion at the wrist. Duplex ultrasound is useful when an obstructive lesion is localized by physical examination, waveform analysis, or segmental pressure recordings. B-mode imaging and color Doppler can further define the characteristics of the lesion and its hemodynamic severity. Finally, measurement of digital PPG tracings can be obtained with and without manual pressure causing temporary occlusion of hemodialysis grafts and fistulae when evaluating arterial steal in patients with renal failure.

ANGIOGRAPHY

Accurate delineation of the arterial anatomy of both arms, from the aortic arch to the digital arteries is mandatory when obstructive lesions are suspected on clinical evaluation or by noninvasive testing. Although conventional angiography remains the gold standard, modern computed tomography angiography (CTA) and magnetic resonance angiography (MRA) has replaced this modality in many practices (Fig. 90-8). In order to obtain comparison, both upper extremities should be imaged. If TOS is suspected, provocative maneuvers are used while obtaining arterial images (Fig. 90-9). Of particular importance is obtaining clear images of the hand circulation. Typically, the deep palmar arch arises from the terminal part of the radial artery and the superficial arch by the ulnar artery. Nevertheless, several variations exist (Fig. 90-10).

MANAGEMENT

5 The specific mode for revascularization used to treat upper extremity ischemia depends on the location of the lesion, its etiology, and the available local resources and expertise. Atherosclerotic lesions affecting the origin of the subclavian or innominate arteries are most frequently treated with percutaneous transluminal angioplasty and stenting. This is more often achieved via a femoral approach but can also be performed using a retrograde brachial or even a carotid approach. Despite its popularity due to being minimally invasive, well tolerated by patients, widely available in the armamentarium of multiple disciplines and having immediate angiographic results that are usually excellent, several disadvantages should be considered when choosing this form of therapy. First, deployment of intravascular devices across the origin of the vertebral artery, across an internal mammary previously used as a coronary bypass and under the clavicle should be avoided due to the obvious possibility of catastrophic results. Second, the long-term durability of intravascular stents in the ostia of the aortic arch is not clearly established. Finally, we have seen an elevated rate of stent fractures in this position.¹⁰ This is likely due to the extreme motion of the aortic arch and the supra-aortic trunks around the cardiac cycle. Alternatively, open surgical bypasses and transpositions can be performed via small incisions in the neck with excellent long-term results. For example, the subclavian artery can be transposed to the common carotid artery using a small transverse neck incision. This procedure allows for preservation of the vertebral artery and its long-term patency rate is virtually 100%.¹¹ A short carotid to subclavian bypass using prosthetic material can also be used with excellent long-term results (Fig. 90-11). Finally, in some patients the best option resides in single or multiple-branched bypasses arising from the aortic arch. A ministernotomy is used to expose the ascending arch and the bypass can be anastomosed to the aorta using a side-biting clamp thus obviating the need for cardiopulmonary bypass (Fig. 90-12).

Figure 90-9. Selective digital subtraction angiography of the right arm in a patient with suspected arterial thoracic outlet syndrome. Subclavian artery stenosis is not seen when injecting contrast with the arm in neutral (A) and moderate abduction (B), but is evident when the arm is hyperabducted (C).

Figure 90-10. Different types of complex superficial palmar arch found on 500 hand arteriograms.

Intervention during the acute inflammatory phase of Takayasu arteritis should be avoided. Steroid and immunosuppressive therapy should be used instead and any intervention should be delayed until the acute, active phase of the disease undergoes remission.¹² This is often indicated by normalization of serologic inflammatory markers. Antiplatelet therapies may lower the frequency of ischemic events. During the chronic phase, reconstruction is carried out using similar techniques as those used for the management of atherosclerotic occlusion (Fig. 90-13).

There is little controversy about the management of patients with arterial TOS. Untreated arterial injury due to repetitive torsion and compression leads to stenosis, poststenotic aneurysmal dilation, and distal embolism. In the majority of cases, evidence of distal embolism with compromise of the arteries of the hand is already present by the time of presentation. Thus, thoracic outlet decompression and/or arterial reconstruction is mandatory. Since the subclavian artery can be compressed at any point from the root of the neck to the pectoralis minor tendon, the decompressive approach depends on the specific anatomy of the patient. The surgical plan depends on the details obtained by imaging studies and the experience of the surgeon. In the absence of anatomic anomalies and with compression demonstrated only during arm abduction and elevation, first rib resection via the supraclavicular approach appears to be the best choice. If chronic compression has caused arterial damage, revascularization is necessary. Interposition grafts from the ipsilateral common carotid to the axillary artery are commonly used. This can best be achieved by a combination of supra- and infraclavicular exposure. Eight-millimeter PTFE grafts tunneled underneath the clavicle or subcutaneously have excellent patency rates. Excision of a cervical rib is usually done whereas full thoracic outlet decompression with scalenectomy is only necessary if concomitant neurogenic TOS exists.¹³

Other occlusive lesions of the subclavian, axillary, and brachial artery are best treated with surgical revascularization. Due to potential compression at the costoclavicular space, the high mobility of the shoulder joint and the caliber of the brachial artery, endovascular approaches are rarely indicated in this

segment of the circulation. The conduit of choice for bypasses in the upper extremity is the saphenous vein. Many different configurations are available. The supraclavicular subclavian artery can be exposed by an incision at the base of the neck and used as inflow for bypasses tunneled subcutaneously over the clavicle and into the brachial artery. Alternatively, an excellent source of inflow is the common carotid artery. The outflow anastomosis can be created in the distal brachial artery, the radial or ulnar arteries in the proximal forearm (Fig. 90-14), or at the wrist and even in the arteries of the hand (Fig. 90-15).

Figure 90-11. A: Right carotid to subclavian bypass performed via a supraclavicular incision using a prosthetic 10-mm conduit. B: CT scan showing patency of the bypass.

Figure 90-12. Aorto to innominate bypass. A ministernotomy is done and a side-biting clamp is used for creation of the proximal anastomosis in the ascending aorta. The distal anastomosis is created at the bifurcation of the innominate artery.

Figure 90-13. Arterial reconstruction on the patient with Takayasu arteritis shown in [Figure 90-3](#). A median sternotomy with bilateral neck incisions was used. The proximal anastomosis was done in the ascending aorta. One branch was anastomosed in an end-to-end fashion to the right subclavian. A second branch was anastomosed to the right carotid (side-to-end) and then tunneled via the prevertebral space and anastomosed end-to-end to the left carotid bifurcation. Finally, a side arm was used to revascularize the left subclavian artery.

Figure 90-14. Large aneurysm of the distal brachial artery treated with a bifurcated bypass created with great saphenous vein. The distal anastomosis (*arrows*) were created into the radial and ulnar arteries just distal to the elbow.

Figure 90-15. Completion angiograms of two different saphenous vein bypasses with distal anastomosis to the palmar arch (A) and radial artery at the snuffbox segment (B).

Figure 90-16. Ulnar artery aneurysm treated with arterial conduit (profunda femoris branch harvested from the thigh) in a patient with hypothenar hammer syndrome.

Patients suffering from hypothenar hammer syndrome with mild symptoms and without an aneurysm can be treated nonoperatively. Padded hand protection, avoidance of further repetitive trauma, tobacco cessation (if applicable), and the use of calcium channel blockers, antiplatelet agents, and/or anticoagulation all have been tried with some degree of success. Surgical intervention can include simple ligation of the aneurysm if there is adequate collateral circulation; typically resection of the affected segment with reconstruction is required (Fig. 90-16).

The management of Raynaud syndrome consists on the use of calcium channel blockers and vasodilators.¹³

CONCLUSIONS

Although atherosclerosis is still the most common cause of upper extremity arterial disease, a myriad of conditions associated with occupational and social risk factors are often the cause of arm and hand ischemia. A complete history and physical examination often discloses a potential etiology and usually points to the anatomic location of the culprit lesion. Bilateral hand ischemia is often associated with systemic conditions, whereas unilaterality more commonly occurs with obstructive lesions. Accurate delineation of the anatomy by the use of imaging modalities is necessary in order to plan revascularization. Multiple endovascular and open surgical options are available for the management of upper extremity arterial disorders.

Chapter 91

Renal and Splanchnic Vascular Disease

Dawn M. Coleman, John E. Rectenwald, and Gilbert R. Upchurch, Jr.

Key Points

- 1 Splanchnic vascular disease is uncommon across the spectrum of vascular surgery practice, but remains central to the specialty.
 - 2 Intestinal ischemia may result from presplanchnic conditions that decrease total mesenteric blood flow (i.e., heart failure and hypovolemia), splanchnic conditions that decrease regional blood flow through the mesenteric circulation (i.e., thromboembolism) or postsplanchnic venous congestion (i.e., mesenteric vein thrombosis and cirrhosis).
 - 3 The most common causes of AMI include: embolization (40% to 50%), arterial thrombosis (25% to 30%), nonocclusive mesenteric ischemia (15% to 20%), and mesenteric venous thrombosis (5% to 15%).
 - 4 Patients with AMI warrant immediate medical management that includes the establishment of adequate intravenous access and hemodynamic monitoring, systemic anticoagulation with heparin, fluid resuscitation, correction of electrolyte abnormalities, and administration of broad-spectrum antibiotics.
 - 5 The progression from minor symptoms to AMI and intestinal infarction is unpredictable; almost half of patients presenting with AMI describe previous symptoms of CMI.
 - 6 Distribution of splanchnic artery aneurysms is as follows: Splenic artery (60%) > hepatic arteries (20%) > superior mesenteric artery (5.5%) > celiac artery (4%) and gastric and gastroepiploic arteries (4%) > ileocolic arteries (3%) > pancreaticoduodenal arteries (2%) > gastroduodenal artery (1.5%) > inferior mesenteric artery (<1%).
 - 7 Renal artery occlusive disease is the most common cause of correctable HTN in adults and the third most common cause of HTN in children and should be considered in the clinical context of: (1) childhood HTN, (2) severe HTN in women <45 years of age, (3) acute and rapid escalation of mild HTN in older patients (>50 years), (4) initial diastolic BP >115 mm Hg, and (5) rapid deterioration in renal function following the administration of antihypertensive therapy (especially with ACE inhibition).
 - 8 Medical therapy remains the mainstay of treatment for RVH with comprehensive goals of care that should encompass glycemic control, cholesterol reduction, smoking cessation, blood pressure reduction, and antiplatelet therapy with aspirin for primary prevention. ACC/AHA guidelines support the use of ACE inhibitors (ACE-I), angiotensin receptor blockers (ARBs), calcium channel blockers, and beta blockers with a class I indication.
 - 9 Several recent clinical trials comparing renal artery stenting to best medical management for renal artery stenosis have failed to demonstrate a conclusive clinical benefit to the endovascular treatment of renal artery stenosis.
-

SPLANCHNIC VASCULAR OCCLUSIVE AND ANEURYSMAL DISEASE

INTRODUCTION

1 Splanchnic vascular disease is uncommon across the spectrum of vascular surgery practice, but remains central to the specialty. Patients often seek medical attention from alternative specialists, emphasizing the importance of cross-disciplinary awareness. Acute mesenteric ischemia (AMI) remains associated with delayed diagnosis and dismal mortality despite notable progress in the diagnosis and treatment of patients with vascular disease. This section elaborates on the current treatment standards

for both splanchnic vascular occlusive disease and aneurysms.

ANATOMY AND PHYSIOLOGY

Three branches of the abdominal aorta perfuse the gastrointestinal tract. The celiac artery originates at the level of T12 and branches into the left gastric, common hepatic, and splenic arteries in a classic pattern in 65% to 75% of cases.¹ Variations are noted in [Table 91-1](#) and may include a true trifurcation of these vessels (25% of the population), replaced and accessory hepatic vasculature, a common celiacomesenteric trunk (<1% of the population), and a persistent ventral anastomosis between the proper hepatic, and a replaced right hepatic artery (off the SMA) denoted as an “arch of Buhler” (<4% of the population). Additionally, the splenic artery can be found to originate directly off the aorta, SMA, left gastric or hepatic arteries. The celiac axis supplies primarily the stomach, duodenum, spleen, liver, and pancreas. The SMA originates approximately 1 to 2 cm caudad to the celiac artery and branches into the inferior pancreaticoduodenal artery, 4 to 6 jejunal and 9 to 13 ileal branches, the middle colic artery, the right colic artery, and terminates as the iliocolic artery. The SMA supplies primarily the lower portion of the pancreas gland, jejunum, ileum, ascending colon, and the proximal half of the transverse colon. The inferior mesenteric artery (IMA) originates off the terminal aorta at the level of L3 and divides into the left colic artery, sigmoid branches and continues as the superior hemorrhoidal artery.¹ This small and most distal mesenteric branch artery supplies primarily the large bowel from the level of the midtransverse colon to the rectum.

Collateralization is a crucial concept when considering the mesenteric circulation. On the grounds of redundancy, given multiple potential sources of collateral flow, at least two of the three major branch vessels must be occluded or have a critical stenosis for mesenteric ischemia to manifest. While arterial collaterals may be small in the physiologic circulation, they have the potential to hypertrophy dramatically when increased flow is required. [Figure 91-1](#) demonstrates several important collateral pathways. The gastroduodenal artery (GDA) and pancreaticoduodenal arcade make up the primary potential pathway for collateral flow between the celiac axis and the SMA. In addition to the aforementioned arc of Buhler, the arc of Barkow consists of arteries in the omentum (SMA branches) that connect to the right and left gastroepiploic arteries (celiac branches). The marginal artery of Drummond is the major collateral route between the SMA and IMA; it lies within the colon mesentery giving rise to the vasa recta. The arc of Riolan lies within a more central portion of the mesentery connecting the middle and left colic arteries. Finally, the IMA may also receive collateral flow from lumbar branches of the aorta, hemorrhoidal branches of the internal iliac artery, and the middle sacral artery.

Table 91-1 Normal and Variant Mesenteric Arterial Anatomy

Vessel	Incidence (%)
Celiac	
–Classic (3 branches)	65–75
–Four branches (including dorsal pancreatic artery)	5–10
–Celiacomesenteric trunk	<1
Hepatic	
–CHA from celiac artery	75
–CHA from SMA	2.5
–Replaced RHA	15–18
■ From left gastric	11–12
■ From SMA	2.5
–Accessory RHA	7–8
–Accessory LHA	2.5
Gastric	
–Left gastric artery	
■ From celiac artery	90
■ From aorta	3
■ Accessory branches from or to left hepatic artery	23
–Right gastric artery	
■ From proper hepatic artery	40
■ From left or middle hepatic artery	40
■ From RHA	10
■ From GDA	8

CHA, common hepatic artery; SMA, superior mesenteric artery; RHA, right hepatic artery; LHA, left hepatic artery; GDA, gastroduodenal artery. Adapted from: Rosenblum JD, Boyle CM, Schwartz LB. The mesenteric circulation: anatomy and physiology. *Surg Clin North Am* 1997;77:289–306.

Splanchnic venous anatomy parallels the arterial system to drain into the portal venous system. The splenic and superior mesenteric veins join to form the portal vein. Hepatic venous blood is drained by the right, middle and left hepatic veins. Portal–systemic connections are multiple and important when considering portal hypertension.

Physiologic intestinal function relies on adequate perfusion and oxygenation of the microvascular splanchnic circulation. Splanchnic blood flow is estimated as 300 to 1,200 mL/min, or about 10% to 35% of the cardiac output, with approximately 70% of this blood flow supplying the mucosa and submucosa.^{1,2} Various intrinsic and extrinsic autoregulatory mechanisms including tissue metabolites, myogenic mechanisms, and the autonomic nervous system ensure adequate gut circulation through both vasoconstriction and relaxation of arterial smooth muscle. The degree of visceral artery dilation and constriction determines the relatively large fluctuations in splanchnic blood flow during fasting and postprandial states.

Duplex ultrasound demonstrates moderate to high arterial resistance in the SMA, with low diastolic flow and slight flow reversal during fasting states. [Figure 91-2](#) demonstrates duplex ultrasonography of normal aorta and SMA. Vessel diameter, flow velocity, calculated volumetric blood flow, spectral analysis, and response to physiologic stimuli allow for precise assessment of the visceral circulation. In the postprandial period (30 to 90 minutes), low-resistance signals are noted throughout systole and diastole, indicative of dilated splanchnic arteriolar beds. Flow reversal does not occur. In contrast, low arterial resistance signals are noted in the celiac artery circulation regardless of feeding, likely due to the influence of the low resistance hepatic vascular bed.

2 Intestinal ischemia may result from presplanchnic conditions that decrease total mesenteric blood flow (i.e., heart failure and hypovolemia), splanchnic conditions that decrease regional blood flow through the mesenteric circulation (i.e., thromboembolism) or postsplanchnic venous congestion (i.e., mesenteric vein thrombosis [MVT] and cirrhosis). Regardless of the mechanism, impaired perfusion of the intestine results in hypoxia-associated sequelae that include cytokine release, free radical production, microcirculatory damage, and bacterial translocation. Mucosal barrier function is compromised secondary to physical disruption of the mucosa, a change in normal intestinal microflora resulting from treatment with broad spectrum antibiotics, and impairment of host immune defenses.³ Intestinal ischemia may rapidly progress to tissue necrosis causing severe metabolic derangements and ultimately multiple organ dysfunction and death. In addition to ischemia-related bowel injury, splanchnic reperfusion exaggerates injury patterns. Reperfusion injury is associated with increased microvascular permeability, increased epithelial permeability with leaking of fluid and molecules into the bowel lumen, and decreased intestinal blood flow.

ACUTE MESENTERIC ISCHEMIA

*“Occlusion of the mesenteric vessels is apt to be regarded as one of those conditions of which ... the diagnosis is impossible, the prognosis hopeless and the treatment almost useless”.*⁴ AMI remains an uncommon event but carries catastrophic potential as illustrated by AJ Cokkinis’ statement above from 1926. Klass is credited with the first successful restoration of arterial blood supply in an attempt to salvage AMI in 1951 by SMA embolectomy.^{5,6} While clear medical and technologic progress has been made in the interim, delayed diagnosis and treatment continues to impede improvements in contemporary patient morbidity and mortality rates that approach 80%.^{6,7}

AMI accounts for <1 in every 1,000 hospital admissions, presents most commonly during the seventh and eighth decades of life, and epidemiologic study suggests that women are affected with three times the frequency of males, at least in part attributed to relative female longevity.⁶ A Swedish epidemiologic study cites an AMI incidence of 12.9/100,000 people years (as diagnosed by autopsy or operation).⁸

3 The most common causes of AMI are referenced above and include: embolization (40% to 50%), arterial thrombosis (25% to 30%), nonocclusive mesenteric ischemia (NOMI) (15% to 20%), and mesenteric venous thrombosis (5% to 15%).^{6,8} Additional causes may include visceral malperfusion associated with aortic dissection, mesenteric arterial dissection, and trauma. Historic mortality rates for AMI are as high as 93%, although more contemporary series suggest in-hospital mortality rates of 17% to 62% and a systematic review of 45 observational studies cites a mean mortality rate of 71.6% for 3,692 patients with AMI.⁸⁻¹³ While there is no validated prediction model for mortality in this clinical setting, authors have shown with logistic regression models that age, duration of symptoms, age-adjusted comorbidity, specific EKG markers, and shock index may be associated with higher mortality.^{12,14,15}

Figure 91-1. Mesenteric collateral circulation.

Patients with AMI complain predominantly of abdominal pain followed by nausea, vomiting, and diarrhea. Pain is often described as “out of proportion” to the clinical examination as tenderness to palpation may be minimal until transmural necrosis of the intestine develops. Patients can be tachycardic and demonstrate melena or heme positive stools. Fever, guarding, and rebound are typically late findings associated with bowel infarction.

Laboratory abnormalities may include hemoconcentration, leukocytosis, lactic acidosis, and elevated anion gap, amylase, aspartate aminotransferase, and lactate dehydrogenase. While a reliable biomarker for AMI remains elusive, D-dimer offers 96% to 100% sensitivity as an exclusionary test for early AMI with low specificity.^{16,17} Intestinal fatty acid binding globulin (I-FABP), α -glutathione S-transferase, and D-lactate are currently promising plasma markers.^{16,18} I-FABP and α -glutathione S-transferase are located in the small bowel mucosa while D-lactate originates from bacteria in the intestinal lumen as a normal product of bacterial fermentation. These markers leak into the blood stream during early ischemia from damaged enterocytes and may offer increased specificity for small bowel ischemia.

Figure 91-2. Mesenteric duplex ultrasound of a normal aorta and SMA that demonstrates moderate to high arterial resistance in the SMA, with low diastolic flow and slight flow reversal during fasting states. AO, aorta; SMA, superior mesenteric artery; PSV, peak systolic velocity; EDV, end-diastolic velocity; RI, resistive index; OR, origin.

Diagnostic work-up often starts with a plain abdominal radiograph which may reveal ileus and vascular calcifications; bowel wall edema (i.e., thumbprinting), pneumatosis (Fig. 91-3), pneumobilia, and pneumoperitoneum may become evident with advanced ischemia and infarction, respectively. High-quality computed tomography angiography (CTA) has become the gold standard for imaging AMI given near-universal availability and its ability to assess for bowel perfusion while excluding alternate sources of abdominal pain. Additionally, “biphasic” CT offers arterial and delayed phase imaging that permits visualization of the portal venous system in addition to arterial stenosis, occlusions, and bowel wall features that support the diagnosis of AMI with a negative and positive predictive value reported up to 96% and 100%, respectively.^{19,20} Duplex ultrasonography, magnetic resonance angiography (MRA), diagnostic peritoneal lavage, and diagnostic laparoscopy may serve as adjuncts for diagnosis but secondary to intrinsic limitations should not be considered first line. Finally, the role for arteriography remains important and will be described further as it allows for simultaneous therapeutic measures.

Mesenteric emboli most commonly affect the SMA given its oblique orientation off the aorta. Most emboli are cardiac in origin; less common embolic sources may include proximal aortic aneurysm, atrial myxoma, and paradoxical embolus secondary to venous thromboembolism with cardiac shunting. Patient history will likely reveal atrial fibrillation, myocardial infarction, congestive heart failure or cardiomyopathy, rheumatic heart disease or ventricular aneurysm. Most emboli will spare the SMA origin and lodge distal to the middle colic artery and early jejunal branches. This pattern of ischemia, in the absence of well-formed collaterals, results in a classic pattern of ischemia that compromises the bulk of small bowel and ascending colon while sparing the proximal jejunum and distal transverse colon (Fig. 91-4).

Figure 91-3. Abdominal radiograph demonstrating diffuse ileus and intestinal pneumatosis (*arrow*) in a patient with acute mesenteric ischemia.

Figure 91-4. Pattern of embolic mesenteric ischemia – SMA emboli typically spare the middle colic artery (*arrow*) and proximal jejunal branches (*bracket*) resulting in an ischemic pattern that spares the jejunum and distal transverse colon.

Acute in situ arterial thrombosis typically coincides with pre-existing atherosclerotic disease. Up to 20% to 50% of patients will describe antecedent postprandial abdominal pain and weight loss consistent with CMI.^{2,6,9} Clinical presentation may be more subacute given the presence of preformed collaterals that are typically absent in cases of embolic AMI. Patient history will likely reveal common cardiovascular risk factors. [Figure 91-5](#) demonstrates the highly calcified aorta of a patient presenting with AMI and chronic celiac artery occlusion, SMA thrombosis (encircled), and IMA occlusion.

MANAGEMENT OF AMI

4 Patients with AMI warrant immediate medical management that includes the establishment of adequate intravenous (IV) access and hemodynamic monitoring, systemic anticoagulation with heparin, fluid resuscitation, correction of electrolyte abnormalities, and administration of broad-spectrum IV antibiotics. Further vasoconstrictive insult with vasopressors should be avoided if possible. Patients with AMI and evidence of threatened bowel viability warrant immediate surgical exploration. Frankly necrotic or perforated bowel should be resected and left in discontinuity to limit contamination while definitive intestinal management should never delay revascularization.

Figure 91-5. CT imaging demonstrating in situ SMA thrombosis in the setting of highly calcified aortoiliac occlusive disease and chronic celiac and IMA occlusions presenting as acute mesenteric ischemia.

SMA thromboembolectomy is the standard technique for embolic disease. [Figure 91-6](#) illustrates anterior exposure of the SMA at the base of the colonic mesentery. Typically venous tributaries, small lymphatics, and autonomic nerve fibers require ligation to facilitate arterial exposure. The inferior pancreatic border may require mobilization for more proximal SMA exposure. The SMA is exposed and controlled proximal to the middle colic artery; the middle colic artery and jejunal branches are similarly controlled. After a therapeutic level of systemic anticoagulation is confirmed a transverse arteriotomy is created sharply ([Fig. 91-7](#)). The proximal SMA is vented; in the absence of robust and pulsatile antegrade flow a balloon thromboembolectomy should be performed with a 3-Fr or 4-Fr catheter. Distal vasculature is fragile and thromboembolectomy is best accomplished with a smaller catheter (i.e., 2 Fr or 3 Fr). During balloon thromboembolectomy the balloon should be inflated with heparinized saline (not air) as the catheter is withdrawn. The same person should control the balloon inflation that is controlling catheter removal. Finally, consider flushing regional heparin or thrombolytic agent directly into the distal SMA and branches. Balloon thromboembolectomy should be repeated until the balloon is withdrawn free of thrombus burden. Following the successful clearance of all macroscopic thrombus the arteriotomy can be repaired primarily with simple sutures of 5-0 or 6-0 monofilament suture placed in an interrupted fashion. Vein patch angioplasty should be considered over primary repair for diminutive vessels.

In cases of SMA occlusive disease with in situ thrombosis, bypass is typically required for successful revascularization. In cases of such acuity, typically single-vessel reconstruction (SMA) is all that is required. While there are multiple options for graft orientation and conduit, a retrograde bypass off the right common iliac artery oriented in a “lazy-C” configuration is most often favored ([Fig. 91-8](#)). The lateral portion of SMA is exposed cephalad to the fourth portion of the duodenum. This exposure requires opening of the peritoneum adjacent to the duodenum with full exposure of the terminal aorta and iliac arteries. Synthetic graft (i.e., 6- or 8-mm externally supported polytetrafluoroethylene) is typically favored over autogenous conduit given its favorable size match, ready availability, and resistance to kinking. Saphenous vein graft may be considered for cases of gross enteric contamination. The terminal aorta or left common iliac artery may also be used for inflow. Antegrade bypass off the supraceliac aorta may be considered in cases of prohibitive anatomy, but this exposure adds additional technical complexity and operative time combined with the physiologic stress of aortic cross-clamping.

Figure 91-6. SMA exposure at the base of the colonic mesentery (*SMA encircled proximal to the middle colic artery*).

Figure 91-7. Illustration of balloon SMA thromboembolectomy through a transverse arteriotomy.

Figure 91-8. Retrograde bypass off the right common iliac artery oriented in a 'lazy-C' configuration.

While surgery has remained the standard of care for AMI over previous decades, a hybrid procedure for SMA thrombosis has become widely embraced for its efficiency and decreased invasiveness for mesenteric revascularization. This approach negates the need for aortic cross-clamping, prosthetic conduit, and difficulty with arterial quality. Retrograde open mesenteric stenting (ROMS) was first described by Milner et al. in 2006 and further popularized by Wyers et al. in a 2007 case series.^{21,22} The infracolic SMA is exposed at the base of the transverse colonic mesentery as previously described for retrograde cannulation following local patch angioplasty with vein or bovine pericardium. This hybrid approach allows for simultaneous assessment and treatment of nonviable intestine with mesenteric revascularization by way of SMA stenting. The largest and most contemporary series on ROMS reports a technical success rate of 93% and primary-assisted patency rates of 91% at 12 months.²³

Regardless of the approach to successful revascularization, intestinal viability must be assessed; this decision is typically deferred for 20 to 30 minutes following reperfusion and aided by Doppler interrogation of the mesenteric arcade, observation of serosal color, and the presence of peristalsis. Adjuncts also include the use of fluorescein with a modified Wood's lamp or perfusion fluorometer.⁶ Nonviable bowel is resected and in cases of unclear viability the intestine may be left in discontinuity, the abdomen left open, and plans for a second-look laparotomy at 24 to 48 hours secured for definitive intestinal management.

Exclusive endovascular treatments for AMI are increasingly reported despite historic concerns that this approach increases time to revascularization, prohibits assessment of bowel viability, and that endovascular failure might delay traditional revascularization thereby worsening patient outcomes. Successful cases of percutaneous mechanical thrombectomy, aspiration thrombectomy, and intra-arterial thrombolysis, with or without adjuvant angioplasty and stenting, have been reported in patients without evidence of advanced bowel ischemia.²⁴⁻²⁹ The largest single center experience with endovascular therapy for AMI reported a success rate of 87%, with failures most often requiring surgical embolectomy.³⁰ These authors compared outcomes following open and endovascular therapies for AMI and identified a reduction in need for laparotomy, length of bowel resected, and morbidity including acute renal failure and pulmonary failure in the endovascular group. Additionally, successful endovascular therapy was associated with improved mortality (36% vs. 50%) and those endovascular failures succumbed to similar mortality rates as the open surgical group. Most recently a National Inpatient Sample (NIS) review identified a significant increase in the utilization of endovascular therapy for AMI and reported that mortality, hospital length of stay, need for bowel resection, and need for postoperative parenteral nutrition were reduced in those patients receiving endovascular therapy in comparison to traditional open surgical revascularization.³¹

Nonatherosclerotic Mesenteric Arterial Occlusive Disease

Intestinal ischemia may result from iatrogenic injury (i.e., arterial dissection or thromboembolism during endovascular techniques), aortic dissection resulting in visceral malperfusion, trauma, inflammatory arteritides, and fibromuscular dysplasia (FMD). Indeed, these patients warrant an individualized approach to treatment. In cases of aortic dissection branch revascularization or aortic fenestration is essential. Traumatic injuries often require urgent surgical repair or revascularization. Inflammatory arteritides are typically managed medically (i.e., immunosuppression) with surgical bowel resection reserved for nonviability.

Mesenteric Vein Thrombosis

Splanchnic vein thrombosis is defined by thrombosis of the portal venous system which includes the superior mesenteric, inferior mesenteric, splenic, and portal veins. The sequelae of such may include bowel or splenic infarction and chronic portal hypertension. MVT is a less common form of intestinal ischemia that may present in a more subacute fashion. While AMI symptoms are similar to those aforementioned, patients with MVT may also complain of days to weeks of a prodrome that includes crampy abdominal pain, distension, nausea, and malaise. Whether thrombosis originates in the small or large splanchnic veins, intestinal infarction requires the involvement of venous arcades and vasa recta resulting in occlusion of venous return, venous engorgement of the bowel wall, cyanosis, and mucosal ischemia that can progress to transmural infarction.³² Idiopathic MVT represents a minority of cases as more than 50% of patients have at least one predisposing risk factor. Risk factors for MVT include heritable and acquired thrombophilia, hypercoagulable states resulting from systemic disorders (including malignancy and heparin-induced thrombocytopenia), and local intra-abdominal processes (i.e., pancreatitis or trauma). A high index of suspicion is necessary for diagnosis given the nonspecific nature of presenting symptoms, signs, and laboratory studies.³² CT imaging with portal phase venous contrast (CT venogram) is the imaging modality of choice. Findings suggestive of MVT include a sharply defined, enhancing venous wall with central low attenuation.^{32,33} MRA, angiography, and laparoscopy are useful adjuncts. Emergent laparotomy should be considered for signs of advanced intestinal ischemia; intraoperatively blood-tinged ascites is likely to be encountered and the bowel will appear dusky, thick, and rubbery. Systemic anticoagulation is the mainstay of treatment as it reduces mortality, decreases recurrent thrombosis rates from approximately 30% to <5%, and decreases mortality associated with recurrent thrombosis.^{32,34–37} Additionally, with anticoagulation most patients will demonstrate partial or complete venous recanalization with time. In the absence of a defined risk factor, patients with MVT should undergo a work-up for thrombophilia. A finite duration of anticoagulation is recommended for those with a reversible provoking risk factor with cessation of anticoagulation encouraged after 3 months; remaining cases of idiopathic MVT or persistent risk warrant indefinite anticoagulation.³⁸ Historically open venous thrombectomy was employed for advanced cases of MVT at the time of laparotomy. More recently various systemic and percutaneous thrombolytic techniques have been applied to cases of large vessel disease; however, no large or well-controlled trials exist to guide recommendations for such over anticoagulation alone.^{32,39–42}

Nonocclusive Mesenteric Ischemia

NOMI results from diffuse mesenteric vasospasm. This rare form of intestinal ischemia most often affects critically ill patients with hemodynamic instability. Risk factors include decreased cardiac output (i.e., heart failure or arrhythmia), hemodialysis, shock, vasoactive medications (i.e., vasopressors or digitalis), and drug abuse (i.e., cocaine). Angiography is required for diagnosis and will demonstrate diffuse vasoconstriction and nonopacification of branch vessels (Fig. 91-9). Treatment centers on improving mesenteric perfusion by optimizing volume status, limiting vasoactive medications and correcting contributing comorbidities. Intra-arterial infusion of vasodilators (i.e., papaverine or nitroglycerin) or IV infusion of glucagon or prostaglandin E₂, which selectively increases splanchnic blood flow, have been advocated in treating this form of intestinal ischemia without robust large or well-controlled trials to support treatment guidelines.^{43–45}

Figure 91-9. Nonocclusive mesenteric ischemia – mesenteric arteriogram revealing diffuse vasoconstriction and nonopacification of SMA branch vessels.

CHRONIC MESENTERIC ISCHEMIA

Symptoms of CMI are often referred to as “intestinal angina.” Ostial stenosis secondary to arteriosclerosis is the most common etiology and patients typically share risk factors of overt atherosclerosis and long-standing tobacco abuse. Additional causes of CMI may include arterial FMD, vasculitis, aortic coarctation, and connective tissue disorders. In light of aforementioned mesenteric collaterals, the responsible anatomic lesions of CMI typically affect at least two of three splanchnic arteries, although isolated lesions of the SMA distal to the middle colic branch may yield intestinal angina by excluding collateralization.² Patients classically present with postprandial abdominal pain that occurs within 30 minutes of eating and may last up to 4 hours postprandial. Consistent postprandial symptoms typically result in the modification of eating habits that may range from the consumption of smaller meals to “food phobia” that subsequently results in weight loss and malnutrition.

5 The progression from minor symptoms to AMI and intestinal infarction is unpredictable; almost half of patients presenting with AMI describe previous symptoms of CMI.⁴⁶ The incidence of CMI also remains unclear. Population studies suggest that up to 18% of individuals over 65 years of age have asymptomatic radiographic mesenteric stenosis.⁴⁷ Duplex ultrasonography should be considered the first-line diagnostic modality for CMI. Specifically, high-grade stenosis of the SMA and celiac artery in a fasting state are suggested by a peak systolic velocity of >275 cm/s and 200 cm/s, respectively.⁴⁸ CTA and MRA support the diagnosis of CMI while offering additional vascular anatomic evaluation such as the presence of aortic aneurysm, calcific burden, and venous anomalies that may impact open reconstruction. Aortography with anteroposterior and lateral views has been commonly cited as the gold standard for diagnosis and allows for simultaneous mesenteric arteriography, manometry, provocative measures (i.e., vasodilator infusion), and intervention (i.e., angioplasty and stenting) as appropriate. This modality is often favored over cross-sectional imaging when an endovascular approach for treatment is being considered over open revascularization. Often patients will present having undergone extensive gastrointestinal work-up (i.e., contrast motility studies, endoscopy, and laparotomy) before the diagnosis of CMI is considered.

MANAGEMENT OF CMI

Treatment goals in the management of CMI include symptomatic relief, restoration of normal weight, and the prevention of bowel infarction. Mesenteric revascularization provides immediate symptom relief in most patients. Classically, open surgical revascularization options consider patient

cardiopulmonary reserve to tolerate aortic cross-clamping and aortic and arterial calcific burden to dictate vascular sites for clamping and sewing. Elective revascularization in the lower-risk patient favors two-vessel (i.e., celiac and SMA) antegrade reconstruction when anatomically feasible. Contingent on vessel calcification, the supraceliac aorta through a transperitoneal approach serves as a preferential target for inflow. After entering the lesser sac, division of the left triangular ligament allows for retraction of the left hepatic lobe. With the esophagus retracted toward the patient's left (confirmed by palpation of the existing nasogastric tube), transection of the diaphragmatic crura exposes the supraceliac aorta. The celiac trunk, common hepatic artery, and splenic artery are exposed at this time. Subsequently with retraction of the transverse mesocolon cephalad, the SMA is exposed as described above at the root of the mesentery. A retropancreatic tunnel is created that courses anterior to the renal vein. The patient is systemically anticoagulated with heparin and the proximal anastomosis can be constructed with partial aortic occlusion. Most often a knitted polyester synthetic graft is utilized for conduit. There are multiple acceptable variations that include the use of two separate aortomesenteric bypass grafts (Fig. 91-10) or the use of a bifurcated graft. It is conventional to utilize a prefabricated bifurcated graft (e.g., 14 × 7 mm) for reconstruction. In this case a short main body is beveled to create the proximal end-to-side aortic anastomosis; the left limb is tunneled through the retropancreatic tunnel and an end-to-side distal anastomosis created next to the SMA; the right limb is subsequently cut to size and beveled to create an end-to-end anastomosis to the celiac artery directly or an end-to-side anastomosis with the common hepatic artery. These authors favor the approach presented in Figure 91-11. A limb of a bifurcated knitted polyester graft is transected off the main body in such a way that there is a phalange created. This limb is specifically utilized for creation of the aorto-SMA bypass, with the phalange incorporated into the proximal aortic anastomosis as shown. The remaining limb is cut to size and beveled accordingly; the proximal anastomosis is constructed end-to-side off the aorto-SMA bypass graft and the distal anastomosis constructed end-to-side to the common hepatic artery. This facilitates a very short celiac limb with a natural lie that may reduce the risk of limb kinking or torsion. Finally, the descending thoracic aorta may serve as an alternative source for inflow when supraceliac aortic anatomy is prohibitive or has previously been utilized for revascularization (Fig. 91-12). For those patients with comorbidity or anatomy (i.e., calcification) that precludes aortic clamping, a retrograde ilio-SMA bypass is favored as described above (Fig. 91-9).

Transaortic endarterectomy is less often utilized in contemporary practice, but may be applicable for those patients with bowel perforation or contamination, hostile abdominal conditions (extensive adhesive disease or abdominal wall hernia), and bulky coral reef aortomesenteric plaque with lower extremity ischemia. A retroperitoneal approach to the perivisceral aorta through a thoracoabdominal incision permits a longitudinal or trapdoor aortotomy, endarterectomy and repair with primary closure or patch aortoplasty as illustrated in Figure 91-13.

Figure 91-10. Two-vessel antegrade aortomesenteric bypass.

Figure 91-11. Two-vessel antegrade aortomesenteric bypass based off the supraceliac aorta using a presewn bifurcated graft.

Figure 91-12. Two-vessel antegrade aortomesenteric bypass based off the supraceliac aorta using two separate grafts.

While historically criticized for high mortality rates (up to 15%), contemporary outcomes following open mesenteric bypass at high-volume centers support mortality rates $<4\%$, likely secondary to technical refinements, improved patient selection and advances in medical, anesthetic, and critical care management.⁴⁹⁻⁵⁶ Open mesenteric revascularization boasts excellent symptom improvement (77% to 100%) with low recurrence rates at 3 to 5 years (0% to 32%) and perioperative morbidity rates approximating 35% to 40%.^{56,57}

Figure 91-13. Endarterectomy of the aorta, celiac and superior mesenteric arteries through a longitudinal trapdoor aortotomy with primary closure.

Endovascular mesenteric revascularization has increasingly become utilized for chronic mesenteric ischemia. Stenting of the mesenteric vessels is recommended over angioplasty alone for favorable anatomy that includes short segment SMA stenosis (<2 cm) with minimal to moderate calcification or thrombus, although some authors support a role for stenting in the treatment of higher-risk and occluded vessels.^{58,59} Endovascular revascularization offers success rates approaching 100% with immediate symptom relief. While perioperative morbidity is notably lower in comparison to open surgical revascularization, endovascular interventions are more likely to result in restenosis, recurrent symptoms, and require reintervention.^{53,60–62} Primary and secondary patency rates approximate 40% and 88%, respectively at 5 years (in comparison to 88% and 97% following open revascularization) emphasizing the importance of patient counseling preoperatively and close surveillance postprocedure.⁵⁶ Two-vessel (celiac and SMA) stenting does not appear to reduce the risk of recurrent symptoms or reintervention when compared to single-vessel (SMA) stenting and moreover, isolated celiac artery stenting carries a higher risk of recurrence.⁶³ Covered stents appear to be associated with less restenosis, recurrence, and reintervention in comparison to bare metal stents.⁶⁴

A large review of mesenteric revascularization from the Nationwide Inpatient Sample between 1988 and 2006 demonstrated increased overall revascularization procedures for CMI.⁶⁵ Additionally, these authors noted that mesenteric angioplasty and stenting not only surpassed open revascularization procedures for CMI in 2002, endovascular interventions more than doubled open procedures by 2005. While endovascular interventions may be associated with decreased mortality, shorter hospital length of stay, and decreased perioperative morbidity, the data are clouded by both the expansion of treatment indications and the fact that a greater risk of restenosis and recurrent symptoms may increase overall interventions. Moreover, these reinterventions for recurrence likely carry a variable risk for in-hospital morbidity and mortality. Regardless, mesenteric stenting has become the first-line therapy for most patients with atherosclerotic CMI and maintains an important role as a temporizing measure to facilitate weight gain in the high-risk malnourished patients (as a bridge to open revascularization) and for those patients with medical comorbidities that would further complicate or prohibit open surgical revascularization.

Median Arcuate Ligament Syndrome

Median arcuate ligament syndrome (MALS) remains a controversial diagnosis, first described in the 1960s.⁶⁶ Chronic abdominal pain is associated with radiographic evidence of celiac artery compression by the overlying fibrous arch of the MAL and adjacent celiac ganglion. The pathophysiology remains poorly understood and evidence suggests both ischemic and neurogenic etiologies for pain.⁶⁷ Gastric tonometry has documented evidence of mucosal ischemia in patients prior to treatment.⁶⁸ The 7% to

21% incidence of celiac artery compression in asymptomatic patients combined with the typical robust mesenteric collaterals and widely patent superior and inferior mesenteric arteries present in these younger individuals favor a neurogenic etiology.^{69,70} Specifically, compression of the celiac plexus somatic nerves by the MAL may produce abdominal pain that is improved with a celiac ganglionectomy that accompanies ligament release or percutaneous celiac plexus block.

Patients with MALS are typically females in their third decade of life. Symptoms most commonly include postprandial pain, weight loss, and less commonly nausea and diarrhea. Diagnosis is supported by duplex ultrasonography that demonstrates elevated peak systolic velocities through the celiac artery on expiration that normalize or improve with inspiration and reverse flow through the hepatic artery.⁷¹ Cross-sectional imaging like CTA and MRA can support the diagnosis as well, and may reveal poststenotic dilation of the celiac artery. Angiography demonstrating dynamic compression or occlusion during peak expiration remains the gold standard for the diagnosis of MALS (Fig. 91-14). Additionally, as MALS remains a diagnosis of exclusion, some authors favor gastric exercise tonometry test and celiac ganglion block to support patient selection.⁷²

Release of the MAL should include complete dissection and skeletonization of both the MAL and surrounding nerve ganglion. This can be accomplished through an open approach whereby the aortic hiatus and celiac artery are exposed through the lesser sac. Additionally, laparoscopic and more recently robotic techniques have been described. The most contemporary literature review and large series suggest immediate postoperative symptoms relief in approximately 80% to 90% of patients.^{67,68,73-78} Adjunctive procedures for celiac artery revascularization are utilized in a minority of cases and may include celiac angioplasty, celiac artery patch angioplasty, and celiac artery bypass (i.e., aortoceliac bypass). Late symptom recurrence approximates 6% and only Reilly and colleagues have demonstrated a reduction in recurrence following MAL release with celiac artery revascularization in comparison to MAL release alone (24% vs. 44%).^{67,79} Multiple authors have highlighted the importance of patient selection for treatment suggesting that specific patient criteria may correlate with successful outcomes including: consistent postprandial abdominal pain, young age, female gender, weight loss >20 lb and anatomic features of poststenotic dilation or increased collateral flow.⁷⁹⁻⁸¹ A reasonable approach may reserve adjunctive revascularization for those patients with objective angiographic pressure or ultrasound velocity gradients following open surgical MAL decompression or those with persistent symptoms following laparoscopic or robotic release.

Figure 91-14. Lateral aortography demonstrating (A) external compression (*arrow*) of the celiac artery on peak inspiration that (B) worsens dynamically (*arrow*) during peak expiration.

Laparoscopic release of the MAL is increasingly employed for MALS.^{67,73,77,78} While no procedure-related mortality has been reported for open or laparoscopic ligament release, there is a 9.1% incidence across series of open conversion for hemorrhage that follows laparoscopic release, which heightens morbidity and mortality risk.⁶⁷ Certainly independent operator learning curve, institutional technical enhancements, and patient selection may strongly affect this result. More recently, safe and effective robotic-assisted MAL release has been reported to offer benefits over laparoscopic release in light of improved visualization, extra degree of motion provided by robotic arms with “wrist movement” and scaled operator movements (including tremor elimination).⁸²

SPLANCHNIC ARTERY ANEURYSMS

Splanchnic artery aneurysms are historically cited as rare and mainly asymptomatic. In the past, most were syphilitic or mycotic, while contemporary visceral aneurysms are largely true aneurysms caused by atherosclerosis or medial degeneration.⁸³ True aneurysms are defined by the involvement of all three arterial wall layers (intima, media, and adventitia) while false aneurysms, or pseudoaneurysms, represent a collection of extravasating blood outside of the artery that remains confined next to the vessel by surrounding tissue. The incidence of splanchnic artery aneurysms is estimated at 0.1% to 2% and autopsy series suggest a prevalence that may approach 10%.^{84,85} A minority of aneurysms present with life-threatening rupture and while historic-associated mortality rates approached 25% to 70%; more contemporary series suggest mortality rates of 15%, possibly reflecting improvements in perioperative management and the increasing use of endovascular techniques.⁸⁶ Most splanchnic aneurysms are asymptomatic however, and diagnosed as incidental findings by cross-sectional imaging.⁸⁷ False aneurysms may carry a higher rate of rupture in comparison to true aneurysms (76% vs. 3% in once series).⁸⁸

The natural history of these aneurysms remains elusive in light of their rarity and anecdotal, mainly institutional and retrospective, evidence to date. Indications for intervention remain conservative, especially as no significant difference has been identified between the diameters of ruptured and nonruptured aneurysms.⁸⁸ Additionally, aneurysm calcification and intraluminal thrombus are not associated with rupture risk. Treatment is recommended for symptoms and size >2 cm or aneurysm diameter three times greater than the respective normal artery. Patients with splanchnic aneurysms generally have 10-year survival rates >80% and open surgical treatment provides excellent, durable long-term results with low perioperative mortality and morbidity following elective surgery.^{86,89,90} While surgical repair has remained the mainstay of treatment, minimally invasive endovascular techniques continue to evolve and are increasingly applied for both elective treatment and that of rupture. Endovascular intervention with local anesthesia offers excellent technical success, negligible morbidity and mortality in elective cases, and brief hospital stays.^{86,88,90–94} Transcatheter embolization of visceral artery aneurysms offers additional advantages that include precise aneurysm localization, assessment of collateral flow, and negate the need for certain (i.e., intrahepatic) difficult arterial exposures.⁸³ Notably, embolization has become the standard of care for splanchnic artery pseudoaneurysm.^{92,95} Additionally, endovascular therapy may offer decreased postoperative morbidity and mortality rates in cases of rupture when compared to open surgery (2.7% to 7% vs. 24% to 29%, respectively).^{86,91}

6 Distribution of splanchnic artery aneurysms is as follows: Splenic artery (60%) > hepatic arteries (20%) > superior mesenteric artery (SMA) (5.5%) > celiac artery (4%) and gastric and gastroepiploic arteries (4%) > ileocolic arteries (3%) > pancreaticoduodenal arteries (2%) > GDA (1.5%) > IMA (<1%).^{84,87} Most patients present in the sixth decade of life.^{87,88} Symptomatic patients will present with abdominal pain and frank hemorrhagic shock with rupture. Rupture may be intra-abdominal, although erosion into a gastrointestinal lumen may result in sporadic gastrointestinal bleeding (i.e., herald bleed) and erosion into adjacent mesenteric veins results in arteriovenous fistulae. The asymptomatic patient inconsistently reveals a bruit on auscultation and rarely a palpable mass on examination. Each splanchnic aneurysm warrants individual consideration.

Splenic Artery Aneurysm

Splenic artery aneurysms account for 60% of all splanchnic artery aneurysms and are the third most common intra-abdominal arterial aneurysm. Their prevalence in the general population is very low approximating 0.16% to 0.8%.⁹⁶ These aneurysms occur two to four times more frequently in women than men and are associated with multiparity.^{83,87,90,96,97} Hormonal and local hemodynamic events likely contribute to the evolution of splenic aneurysms. An etiologic classification system has previously been proposed by *Stanley and Fry* that implicates arterial dysplasia, portal hypertension, local inflammation, and hormonal and hemodynamic events in the pathogenesis of these aneurysms.⁹⁶ Hypertension is a common comorbidity affecting 50% to 60% of patients with splenic aneurysm, and up to 20% of patients will demonstrate concurrent aneurysms affecting alternate arterial beds.^{94,95,98} Additional etiologic risk factors for true aneurysms may include dissection, septic emboli, polyarteritis nodosa, systemic lupus erythematosus, and connective tissue disorders like Ehlers–Danlos syndrome, while splenic pseudoaneurysms are typically attributed to chronic pancreatitis and trauma.⁸⁷ Splenic aneurysms most often arise at branch points off the mid- and distal main splenic artery. Tortuosity of

the main splenic artery is common (Fig. 91-15). The majority (80%) of splenic aneurysms are solitary and saccular, although 90% of patients with portal hypertension will demonstrate multiple splenic aneurysms. Those aneurysms measuring >5 cm are often described as “giant lesions” and appear to be more common in older males.⁹⁹

Splenic aneurysms typically rupture into the lesser sac with limited self-containment. Later hemorrhage into the peritoneal cavity results in cardiovascular collapse and the so-called “double rupture.” The incidence of splenic aneurysm rupture approximates 2% to 5% and is not associated with calcification, blood pressure, or age.^{84,87,95,96} Increased levels of aneurysmal peripheral calcification are associated with smaller aneurysm size at the time of diagnosis, but appear to have no impact on aneurysm growth.⁹⁵ Growth rates among surveyed aneurysms (out to 3.1 years) have been calculated as 0.2 mm/yr.⁹⁵ Rupture-associated mortality is dramatically increased in the peripartum patient (68% to 75% vs. 25%), and associated fetal mortality approaches 100%.^{96,98,100} Rupture in this setting occurs most commonly during the last trimester.⁸³ While historically a strong association between pregnancy and splenic aneurysm rupture was reported, a contemporary series reporting on >67,000 consecutive live births over 5 years identified no cases of splenic artery aneurysm rupture.⁹⁸ There is no apparent role for routine screening for splenic aneurysm in the pregnant patient.¹⁰¹ Rupture risk is increased two fold by liver transplantation, the mortality following which is 50%.^{102,103}

Figure 91-15. (A) CT angiogram and (B) splenic arteriogram revealing a tortuous splenic artery with two large aneurysms affecting the main splenic artery; the distal aneurysm (arrow) has extensive calcification and mural thrombus.

Indications for treatment include rupture, symptoms, size >2.0 to 2.5 cm and any size asymptomatic aneurysm at the time of liver transplantation or in women of childbearing age.^{87,95,104,105} Historically, the open surgical treatment of splenic artery aneurysms included aneurysm resection or splenectomy. Recognizing the immunologic benefits of splenic preservation, arterial ligation, and aneurysm excision is preferred when possible; however, those patients with multiple and perihilar aneurysms may still require splenectomy. Laparoscopic and robotic techniques at ligation, aneurysm resection and splenectomy have become common-place offering negligible risk of open conversion, need for reoperation and mortality.¹⁰⁶⁻¹⁰⁸ Splenic vaccinations and education regarding the need for booster vaccinations at regular 5-year intervals should be provided. Perioperative morbidity and mortality are estimated as 9% to 25% and 1% to 5%, respectively, across series.^{95,96,109-111}

More recently, endovascular therapy has been utilized with increasing frequency for both elective and ruptured cases boasting decreased early morbidity, mortality, and hospital length of stay. While only 2% of all splenic aneurysms were managed with endovascular therapies in 1999, this proportion increased to 70% between the years 2010 and 2013.¹¹¹ Embolization with coils, gelfoam, glue, thrombin, and vascular plugs has been advocated for saccular aneurysms with narrow necks (Fig. 91-16). Larger vessels with complex wide-neck aneurysms may be better approached with covered stents or stent-assisted coil embolization.¹¹² Technical success for endovascular treatment is 93% to 98%, limited primarily by vessel tortuosity that may be overcome with newer, steerable catheters.^{95,111,113,114} Conversion to open surgery is rarely necessary (<2%) to accomplish successful aneurysm exclusion.¹¹¹ Postembolization syndrome (PES) complicates 10% to 30% of cases across series and may include left upper quadrant pain, fever, ileus, platelet dysfunction, leukocytosis, and pancreatitis following embolization with and without radiographic evidence of splenic infarction.^{95,111,114,115} Up to 21% of

patients will demonstrate major splenic infarct and may require reintervention for splenic abscess by way of percutaneous drainage or splenectomy.^{95,113} Portal hypertension appears to increase dramatically the risk of major splenic infarction.¹¹³ With late follow-up, endovascular repair is associated with an average regression in aneurysm size of 1.5 mm/yr.⁹⁵ Late complications may arise at an average rate of 3.7% per year, and there is a 3.2% rate of reintervention per year following endovascular repair.¹¹¹

Figure 91-16. (A) Celiac arteriogram of a 78-year-old woman with a 4-cm splenic artery aneurysm; (B) Splenic arteriogram demonstrating a catheter in the proximal splenic artery. Vascular occlusion devices (*arrows*) have been positioned in the main splenic artery outflow (distal to the aneurysm) and inflow (proximal to the aneurysm) with multiple vascular coils embedded within the aneurysm sac.

Patients with splenic aneurysms have long-term survival rates that approach 90% at 10 years following aneurysm-directed treatments; cause of death is typically unrelated to aneurysm.⁹⁵ The most recent meta-analysis of splenic aneurysm therapies identifies significantly greater technical success balanced with greater 30-day mortality following open repair in comparison to significantly higher rates of acute minor complications, late complications, and reinterventions following endovascular repair.¹¹¹ Moreover, a recent decision analysis investigating the cost-effectiveness of open repair, conservative management, and endovascular repair for splenic aneurysm identified endovascular therapy as the most cost-effective treatment independent of gender and risk profile of the patient.¹¹⁶

Figure 91-17. Reformatted CT angiogram demonstrating a bilobed and calcified hepatic artery aneurysm.

Hepatic Artery Aneurysm

Hepatic artery aneurysms (Fig. 91-17) account for 20% of all splanchnic artery aneurysms, affecting men twice as often as women.^{83,84,117} These aneurysms are mainly solitary and while small hepatic artery aneurysms (<2 cm) are typically fusiform, larger aneurysms will more often appear saccular.¹¹⁷ The vast majority of these aneurysms are extrahepatic with the common hepatic artery and right hepatic artery most often affected; 20% to 30% of hepatic aneurysms however, are intrahepatic.^{84,97,117} Hepatic

artery pseudoaneurysms are increasingly frequent and account for approximately 50% of hepatic artery aneurysms.^{87,97} Pseudoaneurysms may result from diagnostic and therapeutic interventions that require liver penetration (e.g., biliary stents), liver transplantation, and trauma; their incidence appears to be increasing secondary to the more frequent and regular use of CT imaging following blunt liver trauma and hepatobiliary intervention.^{88,97} True aneurysms present most often during the sixth decade of life and proposed etiologic mechanisms include mainly atherosclerosis and acquired medial degeneration. Polyarteritis nodosa, cystic medial necrosis, portal hypertension, infection, arterial fibrodysplasia, neurofibromatosis, and other arteriopathies are less commonly implicated.^{87,117}

As with most splanchnic artery aneurysms, hepatic artery aneurysms rarely cause symptoms. Symptomatic patients will most commonly describe right upper quadrant or epigastric abdominal pain that may radiate to the back, while those patients with rapidly expanding aneurysms may describe abdominal complaints that mimic pancreatitis. Large aneurysms may erode into the stomach or duodenum resulting in gastrointestinal hemorrhage or they may obstruct the biliary tract resulting in biliary colic, hemobilia, and obstructive jaundice.⁸⁷ Additional physical examination findings like a palpable pulsatile mass and bruit are uncommon. Diagnosis is often made incidentally by cross-sectional CT/MRI, ultrasound or arteriography performed for a nonvascular indication.

Rupture appears to complicate a minority of hepatic artery aneurysms (20% to 30%) and results in an equal distribution of hemorrhage into the peritoneum and the biliary tract.^{84,87} Rupture into the biliary tract results in hematemesis, and cholangitis; rarely is there melena and chronic anemia. Rupture-related mortality approximates 35% to 40%.¹¹⁷ The relationship of rupture risk to aneurysm size remains unclear and a small series of 22 patients with a mean hepatic artery diameter of 2.3 cm (range 1.5 to 5 cm) were followed for a mean of 68.4 months without complication.^{87,117} The presence of multiple aneurysms and nonatherosclerotic etiology are proposed risk factors for rupture.¹¹⁷ While historically treatment was recommended for all asymptomatic aneurysms >2 cm in size, some authors have proposed elective intervention for all and any-size nonatherosclerotic aneurysms and for those patients with multiple hepatic artery aneurysms while reserving a more conservative approach for those atherosclerotic hepatic artery aneurysms measuring 2 to 5 cm in size.¹¹⁷

Open reconstruction is favored for aneurysms of the common hepatic artery by way of aneurysmectomy or exclusion. Often revascularization is not required in light of extensive foregut collaterals from the GDA and right gastric artery that preserve hepatic perfusion. When necessary, options for reconstruction may include primary or patch angioplastic closure of the common hepatic artery, aortorenal bypass, and splenohepatic bypass. Proper hepatic artery aneurysms may be treated by aneurysmectomy requiring reconstruction using a saphenous vein interposition graft or simple aneurysmorrhaphy. Distal or intraparenchymal lesions may require resection of the involved liver parenchyma.⁸⁹ Elective open surgical repair is associated with approximately 30% morbidity and negligible mortality.^{90,92,117} Additional options include transcatheter embolization, which may be an especially useful adjunct for intrahepatic arterial aneurysms obviating the need for hepatic lobectomy, and stent graft exclusion for high-risk patients.^{83,87,90,92,94,118} Technical and clinical success rates with transcatheter embolization approach 100% and 79%, respectively and offers efficient control of hemorrhage, shorter hospital length of stay and lower transfusion requirements in cases of rupture specifically.¹¹⁹ Transient success and recanalization is well described however, mandating thoughtful postembolization surveillance.

Superior Mesenteric Artery Aneurysm

Superior artery aneurysms account for up to 7% to 14% of all splanchnic aneurysms, depending on the series.^{84,86,88,90,91} These aneurysms affect men more frequently than women in their sixth decade of life and are mainly solitary.^{84,120,121} SMA aneurysms may result from infection (i.e., nonhemolytic streptococci in bacterial endocarditis), dissection (Fig. 91-18), medial degeneration, atherosclerosis, FMD, vasculitis, connective tissue disorder, and trauma.^{84,88} Additionally, false aneurysms may occur in the setting of pancreatitis and complicated peptic ulcer disease.¹²⁰ Concomitant hypertension is common, affecting >20% of patients with SMA aneurysm, as are associated aortic and peripheral/splanchnic aneurysms.^{90,94,121,122}

While most patients with SMA aneurysm are asymptomatic, abdominal pain is the most common symptom followed by nausea, emesis, GI bleeding, and fever in cases of mycotic aneurysm.¹²⁰⁻¹²² Clinical examination may reveal a pulsatile mass in up to one-third of patients. Diagnosis is most commonly established by CT imaging, although these aneurysms can be appreciated by ultrasound, MRI, and angiography. Complications may include AMI resulting from thromboembolism and rupture.

Rupture risk has historically been considered rare and while rupture-associated mortality has historically approached 50%, more contemporary series cite 30-day mortality rates as low as 12.5% to 38%.^{84,91,121} No comorbidities or aneurysm characteristics have been found to predict rupture risk.¹²¹

Figure 91-18. (A) CT angiogram and (B) intraoperative photo of a large 3.6-cm asymptomatic SMA aneurysm associated with extensive thoracoabdominal aortic and SMA dissection. The aneurysm was repaired by way of an SMA interposition bypass graft using nonreversed great saphenous vein; additionally the proximal SMA dissection flap was sharply fenestrated.

Surgical management of SMA aneurysm most often requires aneurysm excision (or exclusion) with revascularization, most often by way of aortomesenteric bypass.⁹⁰ Both autologous and prosthetic conduits have been described. Autologous conduit is favored in cases of mycotic aneurysm and frank contamination complicating intestinal ischemia while reinforced prosthetic conduit resists compression/kinking and future dilation.⁹⁴ Aneurysmorrhaphy and simple ligation of inflow and outflow vessels (in those patients with appropriate collateralization) have also been described with success.^{84,94,120} Contemporary elective surgical results boast negligible morbidity and mortality.⁹⁴ Endovascular SMA aneurysm exclusion with a stent graft and embolization have been described and increasingly employed for patients with severe cardiopulmonary disease; these therapies remain limited by thromboembolic risks to the collateral circulation, endoleak, and limited long-term follow-up.^{90,121-125} Aneurysms with a small neck distal to the SMA origin may be conducive to transcatheter embolization provided angiographic determination of collateral flow is determined as adequate.¹²¹

Celiac Artery Aneurysm

Celiac artery aneurysms account for approximately 4% of all splanchnic aneurysms affecting men more frequently than women in their sixth decade of life.^{126,127} The incidence in the general population is unknown. Historically celiac artery aneurysms were primarily associated with infection like syphilis or tuberculosis and primarily diagnosed postmortem.¹²⁶ Contemporary etiologic risk factors include primarily atherosclerosis, developmental risk factors such as common celiacomesenteric trunk, arterial dysplasia with medial degeneration, collagen vascular disorder, trauma, and dissection.^{126,127} Concomitant hypertension (20%), aortic aneurysm (18% to 40%), and alternate splanchnic aneurysms (38%) are common in patients with celiac artery aneurysm.^{126,127}

As with most splanchnic artery aneurysms, celiac artery aneurysms rarely cause symptoms.¹²⁷ Symptoms may include abdominal pain, primarily epigastric in location with radiation to the back.¹²⁶ Less common associated symptoms may include nausea, emesis, dysphagia, anorexia, weight loss, and GI bleeding. Abdominal mass and bruit may be appreciated on physical examination. Diagnosis is most commonly established by CT imaging, although these aneurysms can be appreciated by ultrasound, MRI, and angiography.¹²⁷ Historically, rupture complicated approximately 70% of celiac artery aneurysms, resulting in near-certain mortality.¹²⁶ More contemporary estimates suggest rupture rates of 13% with associated 50% mortality.¹²⁶ Hypertension, aneurysm calcification, presence of thrombus, gender, and aneurysm etiology do not appear to influence risk of rupture, which has been described in

aneurysms ranging in size from 2 to 6 cm.^{126,127}

Treatment should be individualized for cases of rupture and elective cases for patient symptoms and aneurysm size >2 cm. Aneurysm ligation and resection, without reconstruction, has previously been endorsed for those patients with adequate foregut collateral circulation. Simple ligation and transcatheter embolization may be considered as life-saving in cases of rupture, but both offer substantial risk of perioperative hepatic and intestinal ischemia, necrosis, and patient mortality.^{126–128} Aneurysmectomy with arterial reconstruction remains the preferred treatment of celiac artery aneurysms. Surgical revascularization may be accomplished by primary arterial–arterial anastomosis following aneurysm resection, direct aortic reimplantation of the celiac artery or its branches, or aortoceliac bypass. Prosthetic conduit may offer superior patency rates in comparison to autogenous reversed saphenous vein, which tends to kink.¹²⁷ Elective surgical repair offers patients symptomatic relief with a 0% to 5% risk of perioperative mortality.^{127,128} Endovascular options for aneurysm treatment are increasingly described including celiac artery stent grafting.¹²⁹

Gastric and Gastroepiploic Artery Aneurysm

Gastric and gastroepiploic artery aneurysms account for approximately 4% to 5% of all splanchnic aneurysms affecting men three times more frequently than women (Fig. 91-19).⁸⁴ Etiologic risk factors include primarily arterial dysplasia with segmental arterial mediolysis and periarterial inflammation like pancreatitis and vasculitis; atherosclerosis when present is felt to be a secondary process.^{83,84,130} Gastric artery aneurysms are 10 times more common than gastroepiploic artery aneurysms. While patients may present with abdominal pain, up to 90% of patients have historically presented acutely ruptured with evidence of GI bleeding more common than intraperitoneal rupture.^{83,84}

Figure 91-19. A: Diagnostic aortogram of an 82-year-old woman with a highly tortuous abdominal aorta, aberrant hepatic arterial anatomy, and two sequential gastric artery aneurysms measuring 10 mm in maximum diameter. B: Completion arteriogram following endovascular embolization.

Treatment is recommended for all gastric and gastroepiploic arterial aneurysms, regardless the size. Arteriogram is invaluable for aneurysm identification preoperatively and operative planning. Surgical management has historically relied on simple arterial ligation or excision without reconstruction while intramural aneurysms required a wedge excision of involved gastric wall.^{84,89} Contemporary literature would suggest that catheter-based embolization of these arteries is the new standard for care with multiple case reports and small series documenting successful aneurysm occlusion with coils and thrombin injection.^{86,131,132}

Jejunal, Ileal, and Colic Artery Aneurysm

Aneurysms of the jejunal, ileal, and colic arteries account for <3% of all splanchnic aneurysms, affecting men and women equally beyond the sixth decade of life.⁸⁴ These aneurysms are associated with medial degeneration, infection, connective tissue disorder, and polyarteritis nodosa with multiple aneurysms identified in approximately 10% of cases.^{84,130,133} Atherosclerosis, when present, is felt to be a secondary process. While patients may present with abdominal pain, most have no symptoms. Rupture may complicate up to 30% of cases resulting in gastrointestinal bleeding and mortality rates that

approach 20%.

Treatment is recommended for all mesenteric branch aneurysms, regardless of the size. Arteriogram is invaluable for aneurysm identification preoperatively and operative planning. Surgical management has historically relied on simple arterial ligation or excision without reconstruction.⁸⁴ Intramural aneurysms and those associated with bowel necrosis required resection of the involved intestine at the time of aneurysm exclusion. Transcatheter embolization has been increasingly utilized, especially for cases of acute rupture and GI bleeding with intestinal necrosis, perforation, and late stricture potential complications.^{134–136}

Gastroduodenal and Pancreaticoduodenal Artery Aneurysm

Gastroduodenal and pancreaticoduodenal artery aneurysms account for <2% of all splanchnic aneurysm.⁸⁴ Men are affected four times more often than women during the sixth decade of life.⁸⁴ Periarterial inflammation resulting from pancreatitis with vascular necrosis or vessel erosion by pseudocyst reflects the most common etiology, while additional causes include arteriosclerosis, congenital medial degeneration, and trauma.⁸⁴ Concomitant celiac artery stenosis and occlusion are common in noninflammatory aneurysms and GDA and pancreaticoduodenal aneurysms are suggested to represent the effect of inordinately high-volume blood flow on branchings of the collateral circulation (Fig. 91-20).^{137–139} Symptoms of abdominal pain are common; additional symptoms may include gastric outlet obstruction and compressive symptoms like nausea and emesis.^{120,140} Rupture is also common, complicating up to 75% of inflammatory and 50% of noninflammatory aneurysms resulting most often in gastrointestinal bleeding and less commonly bleeding into the biliary or pancreatic ductal systems, peritoneum or retroperitoneum.¹³⁹ Rupture-associated mortality approximates 20% to 50%.^{139,141} While it remains unclear if aneurysm size is a risk factor for rupture, rupture has been described at a small median size of 12 mm.^{91,138,142}

Figure 91-20. CT angiogram of an 87-year-old woman with a large 3.4-cm gastroduodenal artery aneurysm associated with celiac artery occlusion.

Open surgical repair remains appropriate for most patients. These aneurysms are most often amenable to simple ligation, aneurysm resection, or aneurysmorrhaphy without revascularization.^{86,90,94,120,139,143,144} Celiac artery revascularization should be considered in select noninflammatory cases. Pancreatitis-associated inflammatory aneurysms may require arterial branch ligation from within the aneurysm sac or pancreatic resection in severe cases. Transcatheter embolization with coils, glue, thrombin, and electrocoagulation has been successfully reported, especially for high-risk patients and those presenting with rupture.^{90,118,139,141,145,146}

Inferior Mesenteric Artery Aneurysm

IMA aneurysms account for <1% of all splanchnic aneurysms. Our understanding of these aneurysms is limited to case reports. Men appear to be most commonly affected.¹²⁰ Atherosclerosis is the most common etiologic factor with additional risk factors including infection, polyarteritis nodosa,

inflammatory arteritides, segmental arterial mediolysis, Behçet disease, and neurofibromatosis.¹⁴⁷ Concomitant celiac and SMA occlusion is common; it has been hypothesized that turbulent blood flow through tortuous marginal arteries originating from the IMA results in a high-flow state, or “jet disorder phenomenon,” and subsequent dilation of the IMA and small collaterals which can lead to weakness of the arterial wall and aneurysmal disease.¹⁴⁷⁻¹⁵⁰ Patients rarely have symptoms. Incidence of rupture approximates 20% with rupture-related mortality approaching 40%.¹⁴⁷

Surgical management in cases of chronic celiac and SMA occlusion requires revascularization of at least one vessel (most commonly the SMA) to minimize intestinal ischemia during IMA aneurysm exclusion and theoretically decrease the risk of recurrent IMA aneurysm postoperatively. IMA aneurysm ligation and/or excision may be sufficient for treatment in certain cases of robust collateral intestinal circulation; in contrast certain cases will dictate IMA revascularization.¹⁵⁰ The role for endovascular therapy remains poorly defined.

RENAL ARTERY OCCLUSIVE AND ANEURYSMAL DISEASE

INTRODUCTION

Renovascular hypertension (RVH) is a well-defined form of secondary hypertension (HTN) that results from renal arterial insufficiency at some level. The pathophysiology of such ischemia is broad, and with both an increasing prevalence of atherosclerotic renal artery occlusive disease and ongoing clinical trials, treatment standards remain in flux.

PATHOPHYSIOLOGY OF RENOVASCULAR HYPERTENSION

Renal artery stenosis resulting in a decrease in mean renal artery perfusion pressure by 10% to 15% stimulates renin release from the kidney. Renin is a proteolytic enzyme produced by the juxtaglomerular apparatus of the kidney that cleaves angiotensinogen to form angiotensin I. Angiotensin I is further processed to angiotensin II by angiotensin-converting enzyme (ACE), which is produced in the lung endothelium and vasculature (Fig. 91-21). Angiotensin II stimulates hepatic production of renin, while providing a continuous negative feedback on the renal release of renin.¹⁵¹ Angiotensin II is a potent vasopressor that increases arterial blood pressure by a variety of mechanisms (Fig. 91-22). Glomerular filtration rate (GFR) is increased via vasoconstriction of the efferent arteriole. Additionally, antidiuretic hormone (ADH) is released from the posterior pituitary gland, causing water conservation. Release of aldosterone from the adrenal glands enhances exchange of sodium in the nephron-promoting volume retention. Finally, angiotensin increases sympathetic tone. All of these mechanisms coalesce to increase arterial pressure by way of arteriolar constriction, enhanced cardiac output, and the retention of sodium and water. Renin has a half-life of 20 to 30 minutes and is primarily cleared by the liver.¹⁵² Normal physiology and sodium balance support a “steady state” of renin activity that is approximately 50% greater in the bilateral renal veins than that in the infrarenal inferior vena cava or peripheral circulation. In cases of unilateral renal artery stenosis, HTN is characterized by renin hypersecretion from the affected kidney and suppression of renin production in the contralateral kidney.^{153,154} Additionally, angiotensin-mediated vasoconstriction causes pressure diuresis of the unaffected kidney. In cases of chronic bilateral or unilateral RVH in those patients with solitary kidney, sodium retention accounts for late reductions in renin secretion.

RENAL ARTERY OCCLUSIVE DISEASE

7 Renal artery occlusive disease is the most common cause of correctable HTN in adults and the third most common cause of HTN in children and should be considered in the clinical context of: (1) childhood HTN, (2) severe HTN in women <45 years of age, (3) acute and rapid escalation of mild HTN in older patients (>50 years), (4) initial diastolic BP >115 mm Hg, and (5) rapid deterioration in renal function following the administration of antihypertensive therapy (especially with ACE inhibition). Renovascular HTN can be notoriously resistant to traditional medical management. Clinical examination may reveal an upper abdominal bruit during systole and diastole.

Diagnostic work-up should begin with serologies to assess renal function (BUN, creatinine) and electrolyte levels. Additional blood hormone levels may help differentiate the diagnosis as high plasma renin activity supports RVH while altered aldosterone, thyroid, and catecholamine levels may indicate endocrine dysfunction. Urinalysis may reveal hematuria or azotemia concerning for intrinsic renal disease. Ultrasonography is the first-line imaging modality for screening patients with RVH. While a

high-quality duplex ultrasound examination in an experienced center is extremely accurate for the diagnosis of main renal artery and ostial stenosis or occlusion, sensitivity is compromised when surveying branch or parenchymal renal arteries and technically challenging in obese patients or in the presence of abdominal gas.¹⁵⁵ An elevated peak systolic velocity (>180 or >200 cm/s) or elevated renal aortic ratio >3.5 (calculated by dividing the peak systolic velocity of the renal artery by the peak systolic velocity of the adjacent aorta) detects renal artery stenosis with sensitivity and specificity of 84% and 97%, respectively.¹⁵⁶ Ultrasonography additionally facilitates a determination of renal length and symmetry, the presence of main renal artery aneurysm (RAA), visualization of adjacent structures (i.e., obstruction, masses, aortic aneurysm), and the assessment of intrinsic vessel renovascular disease by way of the resistive index.

Axial imaging with CTA and MRA are both useful adjunctive imaging modalities that better evaluate stenosis, aneurysms, renal infarcts, dissections, and adjacent structures. These imaging modalities have collectively received a class I indication (level B evidence) as screening tests to establish the diagnosis of renal artery stenosis from the American College of Cardiology (ACC) and American Heart Association (AHA).¹⁵⁷ CTA offers excellent spatial resolution and generated three-dimensional multiplanar images which can be very helpful in treatment planning. CTA however, is limited by the risk of contrast-induced nephropathy and in detecting subtle FMD lesions and branch vessel involvement. Multidetector CTA offers sensitivity and specificity ranging from 86% to 93% and 90% to 100%, respectively.¹⁵⁸ MRA is often favored in younger patients as it offers diagnostic sensitivity and specificity of 97% and 93% without the associated risks of irradiation.¹⁵⁹ Gadolinium is less nephrotoxic than iodinated contrast and while it may be advantageous for those patients with mild renal insufficiency, the risk of nephrogenic systemic fibrosis prohibits the use of gadolinium contrast in those patients with a $\text{GFR} \leq 30$ mL/min/1.73 m². MRA offers the additional benefit of estimating renal perfusion and GFR via calculations of gadolinium clearance.

Catheter-based arteriography remains the gold standard imaging modality for the diagnosis of renal artery stenosis given its unmatched spatial resolution and capacity to detect reliably branch vessel and parenchymal involvement. Additionally, pressure gradients can be measured across a stenosis (a systolic pressure gradient <10 mm Hg is considered normal); intravascular ultrasound may be used to further characterize the renal artery; and any clinically indicated therapeutic interventions can be performed in the same clinical setting.

In cases of complex and equivocal disease, renal vein renin assessments may be used to calculate the renal vein ratio. This ratio reflects a renin comparison between peripheral and renal venous blood. With unilateral renal artery stenosis, the renal vein renin ratio (RVRR) is calculated by dividing the renin activity in venous blood from the affected kidney by that from the (normal) contralateral kidney. A ratio >1.48 supports a functionally relevant renal artery stenosis.^{153,154} In patients with bilateral renal artery stenosis, a renal:systemic renin index (RSRI) is calculated by subtracting systemic renin activity from individual renal vein renin activity and dividing the remainder by systemic renin activity; this index reflects individual kidney renin release.¹⁵³ As aforementioned, there is a steady state of normal renal renin release; normal renal vein renin activity from each kidney is approximately 24% higher than systemic activity (with the total of both kidneys being then 48% higher than systemic activity). Documentation of renin hypersecretion ($\text{RSRI} >0.48$) associated with contralateral kidney renin suppression (RSRI 0 to 0.24) provides a method to differentiate those patients that will be cured or improved of RVH following renal revascularization or nephrectomy.^{153,160}

Captopril scintigraphy (also known as isotopic or captopril renography) and hypertensive urography have fallen out of favor and are no longer recommended as diagnostic studies for the diagnosis of renal artery stenosis.

Arteriosclerosis

Arteriosclerosis is the most frequent cause of RVH affecting men twice as often as women, most commonly in the sixth decade of life.¹⁶¹ Ostial stenosis is most common representing “spillover” of diffuse aortic atherosclerosis, which is present in approximately 80% of patients. Arteriosclerotic renal artery stenosis affects primarily the proximal third of the vessel, with more severe distal extrarenal disease limited mainly to black patients.¹⁶² A contemporary prospective, multicenter, population-based study of cardiovascular health has estimated the incidence of renovascular disease in men and woman aged >65 years as 6% to 7%.^{161,163} Although early angiographic- and image-based studies in selected patients with arteriosclerotic RVH have suggested radiographic progression in approximately a third of renal artery lesions with 10% progressing to occlusion, this longitudinal cohort study reported anatomic

progression to hemodynamically significant disease in only 4% of participants with an annualized progression rate of 0.5% per year and no disease progression to arterial occlusion. Importantly, renovascular disease has consistently been associated with cardiovascular disease across coronary, cerebrovascular, mesenteric, and peripheral vascular beds with a significant and independent relationship noted with prevalent coronary manifestations.^{164–168}

Fibromuscular Dysplasia

FMD is thought to account for approximately 5% to 10% of RVH.^{169,170} FMD is a nonatherosclerotic, noninflammatory vascular disease that may result in arterial stenosis, occlusion, aneurysm or dissection that affects primarily younger women.¹⁷¹ The prevalence of FMD in the general population is unknown, although renal involvement is the most common phenotype comprising 58% to 75% of all FMD cases.^{172,173} FMD until recently has been described by histopathologic classification.^{174,175} By this classification medial fibroplasia is the most common variant accounting for 60% to 90% of FMD cases. Deposition in the media of loose collagen in zones of degenerating elastic fibrils results in the generation of fibromuscular ridges with resultant arterial stenoses alternating with areas of smooth muscle loss with consequent arterial dilation producing a classic “string of beads” appearance angiographically (Fig. 91-23).¹⁷² The distal two-thirds of the main renal artery and its branches are most commonly affected and bilateral disease is common. Intimal fibroplasia accounts for approximately 2% to 5% of all dysplastic renal artery stenoses and presents as a smooth, focal stenosis of the distal main renal artery. This histologic variant is notable for the accumulation of fibrous tissue within the intima with a moderately cellular component with mainly intact or partially fragmented elastic lamina (Fig. 91-24). Perimedial fibroplasia and medial hyperplasia are uncommon variants.

Figure 91-23. A: Right renal arteriogram demonstrating a radiographically subtle focal midartery stenosis (*arrow*); manometry across this lesion revealed a significant pressure gradient. B: Intimal fibroplasia as represented by pronounced intimal proliferation and partial fragmentation of the elastic lamina (*Movat stain, 20 ×*).

Figure 91-24. Aortogram demonstrating a highly irregular perirenal aorta with (A) high-grade bilateral renal artery stenosis

(arrows) successfully treated with (B) bilateral renal artery stents (arrows). The stents are positioned with appropriate overlap into the aorta and are ballooned proximally such that they “flower” into the aorta.

MEDICAL MANAGEMENT OF RENOVASCULAR HYPERTENSION

8 Medical therapy remains the mainstay of treatment for RVH with comprehensive goals of care that should encompass glycemic control, cholesterol reduction, smoking cessation, blood pressure reduction, and antiplatelet therapy with aspirin for primary prevention. ACC/AHA guidelines support the use of ACE inhibitors (ACE-I), angiotensin receptor blockers (ARBs), calcium channel blockers, and beta blockers with a class I indication.¹⁵⁷ While beta blockers are often utilized first line, ACE-Is and ARBs are a mainstay of treatment for most antihypertensive regimens offering 86% to 92% efficacy.¹⁷⁰ Renal function monitoring is essential with the initiation of these agents as the resulting modulation of the renin–angiotensin system with renal artery stenosis affecting a solitary functioning kidney, severe bilateral RAS or advanced chronic kidney disease may result in acute renal failure.

SURGICAL AND ENDOVASCULAR MANAGEMENT OF RENAL ARTERY OCCLUSIVE DISEASE

As RAS may progress with concomitant renal atrophy, renal revascularization should be considered in select cases. Current ACC/AHA guidelines support renal revascularization for hemodynamically significant RAS in several clinical scenarios (Table 91-2).

Arterial Reconstructive Surgery for Renal Artery Occlusive Disease

Historically open revascularization procedures represented the standard of care in the treatment of RVH. The most common option for open renal revascularization remains aortorenal bypass with either autogenous reversed saphenous vein or prosthetic conduit. Alternatives may include (1) nonanatomic renal bypass based off the hepatic, splenic, or iliac arteries, (2) ex vivo renal artery reconstruction, and (3) aortorenal endarterectomy. Nonanatomic (or extra-anatomic) renal artery bypass may benefit those patients with medical comorbidities or aortic anatomy that prohibit aortic cross-clamping and aortorenal bypass.^{176–180} The hepatic artery is used for a right-sided renal reconstruction, the splenic artery for a left-sided reconstruction. Ex vivo renal artery reconstruction may be considered selectively for those patients with complex, distal segmental arterial occlusive disease when balanced with the risk of prolonged operative time, disruption of pre-existing collaterals, and the need for renal cooling.^{181,182} Transaortic and direct renal artery endarterectomy is particularly useful for those patients with bilateral disease, or when arteriosclerotic renal artery occlusive disease affects multiple (i.e., accessory) renal arteries.^{183–185}

Table 91-2 Indications for Renal Revascularization for Hemodynamically Significant Renal Artery Stenosis

Indication	Class Recommendation	Level of Evidence
Asymptomatic bilateral or solitary viable kidney disease	2B	C
Accelerated HTN, resistant HTN, malignant HTN, HTN with unexplained unilateral small kidney, and HTN with intolerance to medication	2A	B
Progressive kidney disease with bilateral RAS or an RAS to a solitary functioning kidney	2A	B
Chronic renal insufficiency with unilateral RAS	2B	C
Recurrent unexplained congestive heart failure or sudden, unexplained pulmonary edema	1	B
Unstable angina	2A	B

Adapted from the 2005 Practice Guidelines for the management of patients with peripheral arterial disease.¹⁵⁷

Open surgical revascularization offers significant blood pressure and renal function improvement in 85% and 50% of patients, respectively across high-volume centers with mortality rates of 2% to

5%.^{169,186–189} While to date there has been no definitive trial comparing open surgical revascularization directly to endovascular therapy, angioplasty, and stenting appears to offer similar effectiveness with lower morbidity and mortality. As such, endovascular measures have replaced surgery as first-line therapy for RVH.^{189,190} Contemporary open surgical renal reconstructions most commonly accompany hybrid endovascular interventions for aortic aneurysmal disease and may be considered for failed endovascular renal revascularization.

Endovascular Renal Revascularization

Since its introduction in 1978, percutaneous renal artery angioplasty (PTA), with or without stent placement, has virtually replaced open surgical reconstruction of arteriosclerotic renal artery stenosis. This technique has exploded in use and for over a decade has been utilized at times perhaps inappropriately as “prophylactic” therapy to treat clinically irrelevant renal artery stenoses.^{191,192} Renal artery angioplasty alone risks arterial dissection from lesion/vessel recoil and early restenosis. Technical success rates of PTA may be as low as 30% to 50% in patients with significant aortic “spill over” lesions. PTA with stenting offers improved success and very reasonable long-term patency with 5-year secondary patency rates >90%.^{193,194}

9 Several recent clinical trials comparing renal artery stenting (RAS) to best medical management for renal artery stenosis have failed to demonstrate a conclusive clinical benefit to the endovascular treatment of renal artery stenosis (Table 91-3).^{195–199} Moreover, RAS is associated with a 1.5% to 8% risk of major morbidity that can include infected hematoma, atheroemboli, renal failure requiring dialysis, and lower extremity limb loss. Significant limitations apply to all of these studies, including design flaws and selection bias.

The appropriate patient for revascularization remains elusive. Most would suggest that those patients with refractory hypertension despite an appropriate medical regimen that includes a combination of ACE inhibition or angiotensin receptor blockade + diuretic + amlodipine with both a hemodynamically significant stenosis by manometric pressure gradient and overall preserved renal mass should still be considered for therapy.²⁰⁰ Notably, evolving data have identified several promising predictors for clinical improvement following renal revascularization including bilateral RAS, mean arterial pressure >110 mm Hg, elevated baseline brain natriuretic peptide, elevated pulse pressure, and renal perfusion as measured by “renal frame count” during angiography (defined as the number of frames required for dye to pass through the renal parenchyma).^{200–204} Ongoing study remains necessary to identify consistent indications for RAS and reliable clinical predictors of successful outcomes following renal revascularization.

Although randomized, controlled trials assessing renal revascularization for renal artery FMD are lacking, current guidelines support the following indications for renal revascularization in this patient cohort: (1) resistant HTN despite an appropriate three-drug regimen, (2) HTN of short duration with the goal being a cure of hypertension, (3) renal artery dissection, (4) RAA, and (5) preservation of renal function in patients with severe stenosis.^{172,205} PTA of the renal artery is the procedure of choice for patients with renal artery stenosis secondary to FMD offering cure rates that approach 50%, with up to 86% of patients improved following PTA, a 20% risk of reintervention, and low risk of minor complications.¹⁷² Hemodynamic significance must be documented by manometry prior to any intervention in these patients and success should be defined by resolution of this gradient postangioplasty. Stenting should be utilized selectively.

Table 91-3 Contemporary Clinical Trials Comparing the Effectiveness of Endovascular Renal Artery Revascularization to Medical Therapy

Trial	Number of Patients	Degree Stenosis	Indications for Renal Artery Revascularization	F/U (yrs)	BP Response	Renal Function Improvement or Stabilization
DRASTIC Trial ¹⁹⁶ (PTA)	106	≥50%	Resistant HTN	1	No difference	N/A
STAR Trial ¹⁹⁵ (RAS)	140	>50%	Renal impairment (GFR <80 mL/min)	2	No difference	No difference
ASTRAL ¹⁹⁷ (RAS)	806	Variable	Refractory HTN or unexplained renal dysfunction with RAS suggested by imaging	5	No difference (systolic) ^a	Decreased progression of renal impairment and lower mean Cr level following revascularization
CORAL ¹⁹⁸ (RAS)	931	≥60% + 20 mm Hg systolic pressure gradient -or- ≥80%	Systolic HTN ≥155 mm Hg despite at least two antihypertensives	43 mo	2.3 mm Hg reduction following RAS (vs. medical therapy) (<i>p</i> = 0.03).	No difference ^b

HTN, hypertension; PTA, angioplasty alone; RAS, renal artery stent; BP, blood pressure; Cr, creatinine.

^aThe decrease in diastolic BP was smaller in the revascularization group.

^bComposite end point included death from cardiovascular or renal causes, myocardial infarction, stroke, hospitalization for congestive heart failure, progressive renal insufficiency, or the need for renal-replacement therapy.

Developmental Dysplasia

Renovascular HTN secondary to renal artery stenosis and abdominal aortic coarctation remain an important cause of pediatric HTN, the natural history of which risks failure to thrive, heart failure, hypertensive encephalopathy, impaired mental development, hemorrhagic stroke, and early mortality.²⁰⁶ It is estimated that 5% to 10% of pediatric HTN may be explained by renovascular disease, following thoracic aortic coarctation and parenchymal renal disease in incidence.^{206,207} The pathophysiology of pediatric renovascular disease remains ill defined, as are the mechanisms by which pediatric renovascular disease occur. FMD and neurofibromatosis type 1 (NF1) are reported as the most common causes of pediatric renal artery stenosis in the western world.²⁰⁸ While the intimal FMD variant described above is uncommon in adults, it is the most common form identified in children with renal artery stenosis. Furthermore, histopathologic review of operative renal artery samples excised from patient with developmental arterial stenosis reveal mainly consistent findings of intimal hyperplasia, medial thinning, and disruption of the elastic lamina (Fig. 91-21).

Open surgical revascularization of renal artery stenosis remains the gold standard for children with developmental lesions.²⁰⁶ Aortorenal reimplantation with spatulation of the renal artery and interrupted suture lines is favored. Alternatively aortorenal bypass using hypogastric artery as conduit is favored over autogenous venous conduit, which can dilate over time to become aneurysmal. Approximately one-third of children will demonstrate associated aortic coarctation and require concomitant patch aortoplasty or aorto-aortic bypass. The University of Michigan experience reports that benefits regarding blood pressure control have accrued in 97% of children with this practice; specifically HTN has been cured in 70%, improved in 27% and unchanged in 3%.²⁰⁶

There may be a role for angioplasty for selected cases of pediatric renal artery stenosis. Certainly this procedure has gained substantial momentum in the past decade. The most robust U.S. experience includes the treatment of 19 hypertensive children aged 2 to 18 years that underwent PTA for renal artery stenosis, of which 7 patients carried the diagnosis of NF.²⁰⁹ While immediate technical success was reported as 91%, only 39% of patients achieved a cure in HTN and an additional 17% of children demonstrated improvement. In total there was a 44% rate of clinical failure and these authors conclude that despite a high rate of technical success, PTA provides a clinical benefit in a smaller majority of children. This is consistent with improvement or cure rates that mainly average 50% to 60% across larger series of pediatric renal artery stenosis treated with PTA.²¹⁰⁻²¹² Notably, renal PTA for the treatment of pediatric RVH due to ostial disease may be complicated by failures requiring remedial operations that are made more complicated by such or nephrectomy.²¹³ Moreover, HTN cure is less likely following remedial operation (24% in comparison to 70% as referenced above).

RENAL ARTERY ANEURYSM

RAAs are rare with an incidence of 0.1% in the general population.²¹⁴⁻²¹⁷ The natural history of RAAs appears to be that of slow to null growth with contemporary series estimating a median annualized growth rate of 0.06 to 0.6 mm.²¹⁸⁻²²⁰ Aneurysm growth rate does not seem to be affected by aneurysm morphology or calcification.²¹⁹ While historic series describe rupture rates as high as 14% to 30% with

associated mortality of 80%, contemporary rupture rates are estimated at 3% to 5% with nongestational mortality <10%.^{214,217,221–224} Most ruptures are diagnosed at the time of presentation and several authors have supported no rupture during the surveillance of nonoperative RAAs.²²⁵

Similar to other splanchnic artery aneurysms, RAAs typically present in the sixth decade with women more commonly affected than men.^{214,221} Most patients will describe no symptoms, although flank pain and hematuria are most common when symptoms do arise. Clinical examination may reveal HTN, renal bruit or a palpable abdominal mass. Aneurysms are typically solitary, saccular, located at arterial bifurcations, and affect the right renal artery more often than the left.²²⁵ Almost 70% of RAA may be associated with FMD and up to 30% of patients will have an alternate arterial aneurysm.^{214,225,226} These aneurysms are commonly identified as an incidental finding by axial imaging; CT is the most common contemporary diagnostic modality, followed by magnetic resonance imaging, ultrasonography, and catheter-based arteriography.²¹⁹ Conventional preoperative arteriography is warranted given the frequency of multiple aneurysms and arterial dysplasia affecting distal branches that may be missed on conventional cross-sectional imaging.

Currently accepted indications for RAA intervention include size >2 cm, female gender within childbearing age, symptoms like pain and hematuria, medically refractory HTN including that associated with functionally important renal artery stenosis, thromboembolism, dissection and rupture. Given the low risk of rupture, slow to null rate of growth, and improved survival following rupture some authors have suggested that a size threshold alone of 2 cm may be antiquated and too aggressive for surgical indication.^{218,219} The potential for gestational rupture remains a valid indication for repair in women of child-bearing age as rupture during pregnancy has been described in aneurysms as small as 1 cm and historic reports suggest maternal and fetal mortality rates that approach 92% and 100%, respectively.^{227,228} Pregnancy has previously been associated with a higher rate of RAA rupture, thought to result from increased vascular flow and hormonal changes resulting in weakening of the vessel wall elastic tissue, no large scale studies report the true incidence.^{215,225} Gestational RAA ruptures occur mainly in the third trimester with only a few case reports of rupture postdelivery.²²⁹ Notably, contemporary outcomes for both mother and fetus may be improving, as there are recent case reports of gestational rupture resulting in both maternal and fetal survival.

Approximately 70% of patients with RAA have HTN, with up to 100% affected in some series.^{214,218,220–224,226,228} Hypotheses for the mechanism of HTN include (1) coexistent renal artery occlusive disease, (2) distal parenchymal embolization, (3) compression or kinking of associated renal artery branches, and (4) hemodynamic changes from turbulent blood flow within the aneurysm results in decreased distal renal artery perfusion.^{214,224} Most series suggest improvement or cure in the majority of hypertensive patients undergoing RAA reconstruction, with postoperative improvement more likely when RVH or renal artery stenosis is identified preoperatively.^{221,225,228}

Open surgical repair remains the gold standard for RAA management as these procedures performed in the elective setting offer low morbidity, negligible mortality, and durable patency.^{218,219,221–224,226,230,231} Options for conventional in situ reconstruction may include aneurysm resection with (1) primary angioplastic closure with or without branch reimplantation, (2) patch angioplasty, (3) primary reanastomosis, (4) interposition bypass, (5) aortorenal bypass, (6) splanchnorenal bypass, and (7) plication of small aneurysms. While complex distal branch lesions were historically treated with nephrectomy, they may rather best be approached with ex vivo repair and autotransplantation which offers excellent technical success without major morbidity or mortality.^{181,232} Most recently, robotic techniques have been introduced that may become more prevalent in future practices.^{233,234} Most authors advocate completion imaging before hospital discharge and long-term follow-up with surveillance imaging.

While traditional endovascular therapies for RAA have utilized coil embolization for distal and parenchymal aneurysms and stent graft exclusion for main renal artery lesions, the indications for endovascular repair have broadened with the introduction of three-dimensional detachable coils, nonadhesive liquid embolic agents (i.e., Onyx), remodeling techniques (which include balloon- and stent-assisted coiling), and flow diverter stents (i.e., the Cardia[®] multilayer stent).^{225,235–237} Technical success is suggested as 73% to 100% across series with highly variable rates of morbidity (13% to 60%) that include primarily radiographic evidence of end organ malperfusion from thromboembolism and subsequent postembolization syndrome, negligible evidence of arterial dissections or renal compromise, and low rates of recanalization requiring reintervention (4% to 13%).^{231,238–240} Although prospective data are lacking, limited comparisons of open surgical and endovascular procedures have reported no significant difference in mortality, perioperative morbidity, freedom from reintervention, decline in

renal function, or length of stay.^{219,231,241}

Chapter 92

Aortoiliac Disease

Loay S. Kabbani, Mitchell R. Weaver, and Alexander D. Shepard

Key Points

- 1 Aortoiliac occlusive disease is mainly the result of atherosclerosis.
 - 2 Claudication is the most common presenting symptom of patients with significant aortoiliac occlusive disease. Some patients may complain of erectile dysfunction. Physical examination typically reveals diminished or absent femoral pulses.
 - 3 Medical treatment of atherosclerotic aortoiliac occlusive disease is key to long-term success. This includes risk factor modification (smoking cessation, control of hypertension, lipid abnormalities, and diabetes mellitus), supervised walking programs and pharmacotherapy.
 - 4 Smoking is the most important reversible risk factor for the development of lower extremity atherosclerotic occlusive disease.
 - 5 Percutaneous transluminal angioplasty, with or without stenting, has become the most common therapy for aortoiliac occlusive disease.
 - 6 Aortofemoral bypass is still the reference standard for reconstruction of advanced aortoiliac occlusive disease.
-

INTRODUCTION

1 Peripheral arterial disease (PAD) is usually a manifestation of systemic atherosclerosis. It affects 3% of the general population older than 40 years and 15% of those older than 70 years, with approximately 50% of patients with PAD being asymptomatic.¹⁻³ Atherosclerotic occlusive disease of the aorta and iliac arteries alone, or in combination with femoropopliteal or tibial occlusive disease, is the most frequent cause of chronic lower extremity arterial insufficiency.

The wide availability of computed tomographic angiography (CTA) and magnetic resonance angiography (MRA) has facilitated diagnosis, anatomic definition and subsequent intervention for aortoiliac occlusive disease (AIOD). Selection of a patient-specific treatment from an increasing array of treatment alternatives, although challenging, will frequently alleviate symptoms and reduce the risk of disease progression. Endovascular and open reconstructive procedures for AIOD have become routine, with low perioperative morbidity and mortality and excellent early and long-term outcomes.

ETIOLOGY

Anatomy and Pathophysiology

The arteries supplying blood to the lower extremities are frequently divided into abdominal, or “inflow,” arteries (the aorta and iliac arteries) and infrainguinal, or “outflow,” arteries (the femoropopliteal and tibial arteries).

Although atherosclerosis is a generalized disease, the earliest lesions tend to occur at arterial bifurcations and in areas of relative fixation, where disruption of normal laminar flow is greatest, and where eddy currents result in areas of low shear stress. Arteriopathies other than atherosclerosis, such as Takayasu’s disease and radiation arteritis, can also involve the aortoiliac system. In slowly developing aortoiliac occlusive lesions, hemodynamic alterations lead to the enlargement of a network of auxiliary or collateral channels around the involved segments; this collateral network is usually sufficient to provide enough blood flow to meet the resting metabolic needs of the lower extremities (Figs. 92-1 and 92-2). These channels, however, do not have the capacity to increase blood flow to the level necessary to meet exercise demands of the lower extremity musculature. The lumbar, hypogastric,

femoral and profunda femoris arteries are interconnected with a large vascular collateral network. Significant other collaterals join the internal mammary artery to the inferior epigastric artery and the superior mesenteric artery (SMA) to the inferior mesenteric artery (IMA) and hemorrhoidal arteries. The latter pathway gives rise to the Arc of Riolan (also known as the meandering mesenteric artery, central anastomotic mesenteric artery, or Haller's anastomosis) and the marginal artery of the colon (also known as the Marginal Artery of Drummond) (Figs. 92-1 and 92-2). The Arc of Riolan connects the proximal middle colic artery with a branch of the left colic artery. The Marginal Artery of Drummond runs in the mesentery close to the bowel as part of the vascular arcade that connects the SMA and IMA.

PRESENTATION

Aortoiliac occlusive disease secondary to atherosclerosis is largely a disease of smokers. Other risk factors include hypertension, lipid abnormalities, diabetes mellitus, male sex, older age, and genetic predisposition. Smoking is the most important reversible risk factor for the development of lower extremity atherosclerotic occlusive disease.⁴⁻⁶ Patients with symptoms of AIOD usually present in their 50s and 60s, whereas patients with infrainguinal disease or multilevel disease (AIOD + infrainguinal) generally present in their 70s.⁷

2 Claudication (Latin *claudicare* = "to limp") is the term used to denote the characteristic exercise-induced, cramping pain in the muscles of the lower extremity that results from demand ischemia. Claudication is the most common presenting symptom of patients with significant aortoiliac disease. Induced by ambulation and quickly relieved by rest, claudication is usually described as a cramping pain or easy fatigability of the involved muscle groups. Although patients with aortoiliac disease classically present with claudication of the thighs, hips, and buttocks, a significant number complain of calf claudication or have significant overlap. Erectile dysfunction in men secondary to reduced hypogastric perfusion is another common complaint and may be found in as many as 30% to 50% of men with AIOD.⁸ The combination of bilateral lower extremity claudication, atrophy of the lower extremity musculature, impotence, and diminished or absent femoral pulses is known as Leriche syndrome, after the French physician René Leriche.⁹

Figure 92-1. A,B: Major visceral and parietal collateral networks that may become prominent with aortoiliac occlusive disease.

Figure 92-2. CTA with 3D reconstruction demonstrating severe aortoiliac occlusive disease with juxtarenal aortic occlusion. Note the extensive collateral networks reconstituting the inferior mesenteric artery (*red arrow*: marginal artery) and femoral arterial segments (*blue arrow*: inferior epigastric artery) (*green arrow*: subcostal arteries and superficial iliac circumflex artery collaterals).

Physical examination typically reveals diminished or absent femoral pulses. A bruit auscultated over the groins or lower abdomen is not specific for critical stenosis. Severely diseased, calcified femoral arteries may be palpable as firm, tubular structures in the groins. Normal femoral and distal pulses may be palpable, even in the presence of hemodynamically significant aortoiliac stenosis. These pulses, however, rapidly disappear following ambulation, as the increased flow demands of the exercising leg muscles lead to lowered peripheral vascular resistance and reduced distal arterial pressure. Patients with longstanding aortoiliac atherosclerosis may have disuse atrophy of the lower extremity musculature. Other common signs of lower extremity arterial occlusive disease include trophic changes, such as hair loss on the legs or toes, and thin, shiny skin on the feet; patients with severe reductions in pedal blood flow may display pedal rubor on limb dependency, coupled with pallor on elevation.

Critical limb ischemia (CLI) symptoms manifest in the lower leg or foot as ischemic rest pain, nonhealing wounds, or gangrenous changes. Such symptoms may be a manifestation of AIOD alone but almost always occur in combination with more distal femoropopliteal/tibial disease (i.e., multilevel arterial occlusive disease). In the absence of infrainguinal disease, aortoiliac collaterals are usually capable of maintaining adequate resting distal tissue perfusion.

Acute arterial occlusions from emboli lodging at the aortic, iliac or femoral bifurcation do not allow collateral pathways to mature and compensate for the sudden loss of blood supply. This situation leads to the acute onset of symptoms, with the resulting 5 “Ps” of acute ischemia: pain, pallor, pulselessness, paresthesia, and paralysis. Cholesterol crystal embolism, or “blue toe” syndrome, occurs when debris breaks free from an aortic, iliac, or more distal plaque, releasing platelet microthrombi, cholesterol crystals, and other atheromatous material into the arterial lumen.¹⁰ Downstream embolism into the microcirculation of the lower extremities can produce dermal discoloration in a characteristic reticular pattern (livedo reticularis), digital ischemia, or even gangrene (Fig. 92-3). Such patients usually have palpable pedal pulses. Embolic events can occur spontaneously or can be induced by interventions, such as guidewire manipulation (e.g., during angiographic procedures or placement of an intra-aortic balloon pump) or clamping an artery with unstable plaque during open vascular surgery.

Clinical Pathologic Types of Aortoiliac Disease

Different patterns of AIOD have been classically identified on preoperative imaging studies.¹¹ Disease confined to the distal infrarenal aorta and common iliac arteries, classified as type I, accounts for only 10% of patients with inflow disease. Patients with type I disease are younger (in their 50s and 60s),

more frequently female, and typically have a normal life expectancy.^{12,13} These patients usually present with complaints of disabling claudication in the buttocks, hips, and thighs. Such localized disease may be amenable to percutaneous transluminal angioplasty (PTA) or, as was sometimes practiced in the past, aortoiliac endarterectomy.

Type II aortoiliac disease is more extensive and more common; the atherosclerotic plaque extends distally into the external iliac arteries and may reach the common femoral bifurcations. Such patients experience worse claudication than patients with more localized disease and may present with CLI. They are usually men, present on average a decade later in life (60s and 70s), than patients with type I disease, and tend to have diabetes, hypertension, and concomitant cerebrovascular, coronary, and visceral atherosclerosis.¹² As a result, these patients have a reduced life expectancy.^{13,14}

Figure 92-3. Digital atheroembolization progressed to gangrene.

Type III disease is a combination of aortoiliac and femoropopliteal and/or tibial disease. These patients with multilevel disease are usually older than those in the other two groups and present more frequently with symptoms of CLI.¹²

One other pattern worthy of mention is aortoiliac hypoplasia. The term *small aortic syndrome* or *hypoplastic aortic syndrome* may also be used. This pattern is encountered in young to middle-aged women who smoke cigarettes. The infrarenal aorta and iliac arteries are unusually small in caliber and hence prone to significant narrowing, even with modest disease. Operative treatment of such patients can be particularly challenging.¹⁵

In response to the rapidly evolving patterns of treatment of AIOD and the increasingly prominent role played by endovascular methods, the Trans-Atlantic Inter-Society Consensus for the Management of PAD (TASC II) has classified AIOD into four types, A through D ([Table 92-1](#)).¹⁶ The value of this classification derives from its use as a template for reporting standards and as a guideline to help direct treatment decisions. Patients with focal disease (TASC II types A and B) usually benefit from endovascular interventions, while those with more advanced disease (TASC II types C and D) are usually best managed with open surgical revascularization. However, evolving endovascular approaches are now being applied to these advanced lesions as well, with acceptable results.¹⁷ This is especially true for high-risk patients with TASC C and D disease presenting with CLI, who frequently have significant comorbidities, such as severe chronic obstructive pulmonary disease, nonreconstructible coronary artery disease, or a low cardiac ejection fraction. Although this approach may lead to less durable results than open surgical options, it is less morbid. To simplify the most current widely accepted strategy, the surgeon should apply endovascular treatment methods for type A and B patients, and lean toward open surgery for type C and D disease.

DIAGNOSIS

In most cases, diagnosis of significant AIOD and its severity can be made on the basis of history and physical examination alone. A clinical diagnosis, however, should be supplemented by noninvasive vascular testing. Such tests provide valuable information by confirming the presence of disease, assessing the degree of ischemia, objectively documenting the arterial segment(s) involved, and establishing a baseline from which the patient can be followed and appropriate interventions planned. Treatment results can be assessed by repeated testing. Such information is particularly useful in a patient with an equivocal history or physical examination. Formal imaging studies (CTA, MRA, and arteriography) are usually reserved for those patients considered for intervention.

Noninvasive Vascular Testing

Segmental Doppler-derived pressure measurements or pulse volume recordings are useful for demonstrating the physiologic significance of disease and can help localize hemodynamically significant lesions. Measurement of systolic arterial pressures at different levels of the lower extremity with a continuous wave Doppler flow probe is the simplest and most useful noninvasive method to assess arterial occlusive disease. The ratio of the ankle systolic pressure (measured at either the dorsalis pedis or the posterior tibial artery) to the brachial systolic pressure (using the higher of the two brachial pressures) is the ankle-brachial index (ABI), or pressure ratio, and is a good measure of the degree of ischemia present. Normal ABIs are generally equal to or slightly greater than 1.0 (Fig. 92-4). Peripheral arterial disease is designated when the ABI is ≤ 0.95 . Patients with claudication usually have ABIs ranging from 0.50 to 0.90, whereas patients with rest pain, tissue loss, or gangrene have ABIs of < 0.50 . Some patients with claudication, as a result of excellent collaterals, may have ABI of > 1.0 at rest.

Table 92-1 TASC II Classification

Type A: Limited stenoses of the common or external iliac arteries	
Type B: Short stenosis of the infrarenal aorta and short stenosis or occlusion of the iliac arteries	
Type C: Advanced stenosis and/or occlusions of the iliac arteries, especially when calcified	
Type D: Infrarenal aortic occlusion sometimes with multiple iliac occlusions and stenoses or associated aneurysm disease	

Figure 92-4. Segmental pressure measurements typical of normal results (A) and aortoiliac occlusive disease (B).

Determination of limb systolic pressures at different locations (with the “four-cuff” technique, where pressures are measured at the upper thigh, lower thigh, calf, and ankle) provides information concerning which arterial segments are involved with occlusive disease (Fig. 92-4) and helps define the presence of inflow artery disease, outflow (runoff artery) disease, or a combination of the two. A pressure drop of more than 20 mm Hg between adjacent levels indicates significant disease within the intervening arterial segment. A reduced upper thigh pressure signifies occlusive disease in the aortoiliac or common femoral segments.¹⁸

In patients with extensive calcification in the walls of the tibial arteries (as is frequently seen in diabetes mellitus or end-stage renal disease), the ankle pressures may not be interpretable because the vessels are too “stiff” to be properly compressed by the externally applied cuff. In this situation, the pressure in the digital arteries of the great toe can be measured, since these small vessels are generally spared calcification. A toe pressure of less than 30 mm Hg indicates severe ischemia.¹⁹ Inspection of the Doppler-derived arterial waveforms can provide additional information.

Patients with claudication occasionally have normal or nearly normal ABIs. As described previously, in such cases the arterial stenosis is not severe enough to cause a pressure drop in the limb at rest but does produce a significant hemodynamic change under conditions of higher flow rates when the distal vasculature dilates, as occurs with exercise. When the distal pressure drops because of vascular dilation, the stenosis prevents increased blood flow into the extremity so that a significant distal pressure drop results. The classic treadmill test involves walking on a treadmill at 1.5 miles per hour at a 14% incline for as long as the patient can go, up to 5 minutes. ABIs are measured before and after a treadmill exercise; a drop of 15% or more in the ABI following exercise is indicative of a hemodynamically significant occlusive disease.¹⁸

Duplex scanning of the aorta and iliac arteries has been advocated by some as a noninvasive diagnostic tool. Accurate imaging of the abdominal arteries, however, is difficult because of their deep retroperitoneal and pelvic locations, which can be further degraded by body habitus and overlying bowel gas. These problems have limited the widespread use of this modality.²⁰ Arteriography, CTA, and MRA may be used for diagnosis, but are usually performed when interventional therapy is contemplated, and are, therefore, discussed later.

Differential Diagnosis

The diagnosis of AIOD is usually straightforward, but occasional diagnostic difficulty may arise when other causes of lower extremity pain are present. Irritation of lumbosacral nerve roots by spinal stenosis or intervertebral disc herniation may cause buttock and leg pain that is associated with activity. Such symptoms (neurogenic claudication), however, usually cannot be reproduced at the same level of

activity, frequently occur when the patient is standing, and are relieved only by sitting or lying down. In addition, the pain is usually in a classic sciatic distribution.

Degenerative arthritis of the hip joints may produce similar buttock, hip, and referred thigh pain. There is usually a history of morning stiffness that progressively improves over the course of the day. Physical examination typically reveals tenderness directly over the hip joint that is exacerbated by moving the joint.

Algorithm 92-1. Patient with symptomatic aortoiliac occlusive disease.

Peripheral neuropathy, particularly that associated with diabetes mellitus, may masquerade as ischemic rest pain.

In all these situations, segmental limb pressure measurements, with or without stress testing, can be helpful in determining the contribution of arterial occlusive disease to the patient’s symptoms.

TREATMENT

The aims of therapy in AIOD are to relieve symptoms and, in cases of CLI, to prevent limb loss (Algorithm 92-1). Medical therapy should be instituted in all patients with atherosclerotic disease but is insufficient as sole therapy in patients with limb-threatening ischemia.

Medical Therapy

3 Atherosclerosis is a systemic disease. Medical therapy is, therefore, key to reducing the risk associated with cardiovascular death in these patients. Risk factor modification, including treatment of diabetes mellitus, control of hypertension, and treatment of hyperlipidemia, and finally modification of lifestyle including cessation of smoking, diet, and exercise, are perhaps the most important components of the care of patients with atherosclerotic disease. Although risk factor control will not reverse the atherosclerotic process, it does limit disease progression; furthermore, some data indicate that smoking cessation lessens the severity of symptoms in many patients.²¹

Smoking Cessation

4 Smoking is associated with a subclinical inflammatory reaction.²² The degree of damage caused by smoking is directly related to the amount of tobacco consumed. The TASC II consensus recommends that: “All patients who are smokers or former smokers should be asked about the status of tobacco use at every visit. All patients should be strongly advised to stop smoking by their physicians. All patients should be offered pharmacotherapy, behavior modification, referral to a smoking cessation program, and counseling.”¹⁴ Smoking cessation alters the progression of the atherosclerotic process and may even reduce the severity of claudication^{23,24}; Furthermore, it is an important step to reduce postoperative complications.^{25,26}

Exercise

Supervised exercise programs have been consistently demonstrated to improve walking time and walking distance.²⁷ Home and community-based therapy are effective for improving walking tolerance but are less effective than formal supervised exercise programs and are associated with a high dropout rate, underscoring the need for ongoing psychological support.^{22,23,28} Outcomes of supervised exercise

programs have been shown to be similar and longer lasting than those of endovascular interventions for mild claudication.^{24,25} Patients are usually advised to walk until the pain occurs, rest until the pain subsides, and repeat the cycle, to a total of 30 minutes a day, three to five times per week. A 3- to 6-month trial of exercise should be initiated before intervention is considered in patients with intermittent claudication.

Diet

A well-balanced diet with low salt, low fat, and moderate amounts of added sugar intake, as per the American Heart Association guidelines, reduces the risk of chronic diseases in general, and cardiovascular disease in particular, and should be followed.²⁶

Glycemic Control

The Trans-Atlantic Inter-Society Consensus (TASC II) consensus document recommends aggressive blood glucose control, with a target A1C goal of <7.0%, and as close to 6.0% as possible.¹⁶

Antiplatelet Therapy

Some form of platelet inhibition should be considered for all atherosclerotic patients in order to reduce the risk of myocardial infarction, stroke, and death.²⁹ Aspirin is the agent of choice, but clopidogrel may be used if aspirin is not tolerated. The effectiveness of antiplatelet therapy in reducing symptoms of claudication is not yet established; however, the risk of PAD progression requiring revascularization is significantly reduced by antiplatelet therapy, compared with placebo.³⁰ Adding aspirin to clopidogrel does not reduce major vascular events. However, the risk of major life-threatening bleeding is increased.³¹

Antihypertensive Therapy

Antihypertensive therapy reduces mortality from atherosclerotic cardiovascular disease. It is, therefore, recommended in the TASC II consensus document, despite the lack of data substantiating that antihypertensive therapy alters the progression of PAD.¹⁶

Lipid-Lowering Therapy

Lipid-lowering therapy with at least a moderate dose of a statin medication is recommended for all patients with atherosclerotic cardiovascular disease, irrespective of the baseline low-density lipoprotein-cholesterol. Lipid-lowering therapy reduced disease progression (as measured by arteriography), helped alleviate symptoms, and improved total walking times and pain-free walking distance.³²

Other Pharmacologic Therapy

Cilostazol and naftidrofuryl can be valuable adjuncts in selected patients with severe lifestyle-limiting claudication.^{33,34} A therapeutic trial (3 to 6 months) may be tried. Although the mechanisms of action of these agents are unclear, a modest but significant reduction in claudication symptoms has been shown in controlled trials. Benefit has not been firmly established for other agents.

Indications for Revascularization

Revascularization is clearly indicated in patients with CLI; without intervention, these patients can progress to limb loss in a fairly short period of time. At 1 year following onset of CLI symptoms, it is estimated that 25% of patients will lose their limb, 25% will suffer a cardiovascular death, and 50% will be alive with their limbs intact.^{35,36} Per year, 1% to 2% of patients with claudication will progress to CLI.³⁶

Patients with significant or repetitive atheroembolism from an aortoiliac source represent a group that clearly benefits from early operative intervention. Removal or bypass of the culprit lesion(s) eliminates the risk for further macro- and microembolism.

The treatment of patients with claudication secondary to AIOD remains somewhat controversial and must be individualized. Patients with mild to moderate symptoms can usually be treated medically with satisfactory results, while patients with severe, disabling, and lifestyle-limiting symptoms of claudication can benefit from revascularization therapy.

Preintervention Imaging Studies

Once a decision has been made to proceed with revascularization therapy, imaging studies are paramount for developing a treatment strategy.

Figure 92-5. CTA 3D reconstruction showing left iliac artery chronic total occlusion (*red arrow*).

Computed Tomographic Angiography

CTA with reformatting requires the intravenous administration of iodinated contrast material, followed by a timed CT scan of the pertinent anatomy. The images are then processed into coronal, sagittal, and three-dimensional image planes (Figs. 92-2, 92-5 to 92-7). For most patients, 120 mL of iodine contrast is used (300 to 370 mg of iodine per milliliter of contrast). Sensitivity and specificity are greater than 92% and 93%, respectively, in detecting >50% stenosis. The main drawbacks of CTA are the ionizing radiation and the use of iodinated contrast, which can cause contrast-induced nephropathy.³⁷

Figure 92-6. A: CTA 3D reconstruction demonstrating right common iliac artery chronic total occlusion (*red arrow*) and severe left common iliac artery stenosis (*blue arrow*). B: Abdominal aortogram redemonstrating right common iliac artery chronic total occlusion and left common iliac artery stenosis. Note successful wire traversal of the right common iliac artery occlusion (*red arrow*). C: Abdominal aortogram demonstrating successful endoluminal bilateral common iliac artery revascularization following percutaneous balloon angioplasty and stent placement. Note the “kissing” stents in the distal aorta (*red arrow*).

Figure 92-7. A: A midline abdominal incision and bilateral groin incisions overlying the common femoral arteries offer exposure for performance of aortobifemoral bypass. B: This image demonstrates an end-to-end proximal aortic to graft reconstruction with the respective graft limbs anastomosed end to side to the common femoral arteries. C: Computed tomographic angiographic postprocessed and reformatted image demonstrating open aortobifemoral arterial reconstruction of juxtarenal aortic occlusion (see Fig. 92-2, preoperative image) with prosthetic bifurcated graft. Note endarterectomy of aorta immediately distal to renal arteries (red arrow), followed by proximal end-to-end anastomosis between graft and aorta (blue arrow). Distal anastomosis to femoral arteries is performed in end to side fashion (green arrows).

Magnetic Resonance Angiography

Contrast-enhanced MRA uses intravenous administration of paramagnetic gadolinium-based agents. With good technique, contrast-enhanced MRA has a sensitivity of 80% to 97%, and a specificity of 73% to 96% (Fig. 92-8).³⁸ The disadvantage of MRA is that it cannot be used in patients with metallic implants such as pacemakers and patients with claustrophobia. Furthermore, in patients with moderately severe renal dysfunction (glomerular filtration rate of <60 mL/min/1.72 m²), concerns for nephrogenic systemic fibrosis secondary to gadolinium limit the use of this technology in this patient population.³⁹

Digital Subtraction Arteriography

Abdominal aortography, with or without demonstration of the arterial tree below the inguinal ligament (“runoff”), is performed after a full workup is completed and may be part of the therapeutic intervention. This procedure is most commonly performed via the femoral artery with the better pulse by means of a retrograde Seldinger technique. When neither femoral artery is available, an upper extremity approach may provide good access. Hemorrhage, local hematoma, pseudoaneurysm, arterial thrombosis, or distal embolism of thrombus or atheromatous debris can occur in up to 0.8% of diagnostic procedures and in up to 6% of therapeutic procedures.^{40,41} Anteroposterior views of the

aortoiliofemoral segments demonstrate the extent of the occlusive process and the pattern of collateral formation. Oblique views of the iliac and femoral arteries are frequently necessary to document posterior wall plaques and stenoses at the origins of the hypogastric and deep femoral arteries. Views of the “runoff” arteries to at least the midcalf level are required to assess the degree of associated infrainguinal occlusive disease. In cases of CLI, visualization of the pedal circulation is also necessary. In patients with borderline kidney function, carbon dioxide may be utilized as a contrast agent.

Figure 92-8. MRA of a patient who had an aortobifemoral bypass. Note the proximal anastomosis (*thin arrow*) and the distal anastomosis (*thick arrows*). Also note the retrograde flow into the iliac arteries.

Occasionally, the hemodynamic effect of a stenosis or series of stenoses along an iliac arterial segment may be difficult to determine, even with oblique views. When the significance of a stenosis remains in question, pressures proximal and distal to the lesion(s) can be measured. A systolic pressure gradient of more than 10 mm Hg (or a 5 mm Hg mean gradient) across the stenosis is indicative of a hemodynamically significant lesion.⁴² For borderline cases, distal pressure measurements can be obtained before and after interarterial injection of a vasodilator (e.g., 100- to 200- μ g nitroglycerin or 25-mg papaverine) to simulate the hyperemic hemodynamics of exercise. A pressure drop of more than 15% systolic pressure (or around 20 mm Hg) during hyperdynamic flow simulation is considered indicative of a hemodynamically significant stenosis.⁴²

The information supplied by CTA, MRA, or arteriography is crucial to the success of a revascularization procedure. In addition to providing a detailed “road map” of the exact arterial segments involved, such imaging identifies associated anatomic variations (e.g., accessory renal arteries) and aortic wall characteristics (e.g., extensive calcification and ulcerated plaque), which may alter the operative approach and the conduct of the procedure. During an open revascularization procedure, a surgeon who knows that the aortic wall just below the renal arteries is heavily diseased with ulcerated plaque may, for example, opt to control the aorta at a more proximal level rather than risk dislodging atheromatous debris with standard infrarenal aortic clamping. Similarly, documented occlusive lesions in the visceral or renal arteries (e.g., a patent IMA with a large “meandering mesenteric artery”) may best be addressed at the time of aortic reconstruction, or require particular attention to avoid complications.

Preoperative Evaluation

Evaluation of patients for whom aortoiliac revascularization is being considered should include a careful assessment of overall operative risk. Age per se is not a contraindication to an open aortic reconstruction, if it is required. A less invasive procedure of more limited durability, however, may provide a similarly excellent outcome in a patient with reduced life expectancy. Patients with significant AIOD may have atherosclerotic occlusive disease in other vascular territories (e.g., coronary and cerebral) that can increase their operative risk. The detection and treatment of significant coronary artery disease is particularly important, because myocardial infarction is the leading cause of both perioperative and late mortality. In patients with significant aortoiliac disease, more than 50% have

clinical or electrocardiographic evidence of coronary disease.⁴³ In the Coronary Artery Revascularization Prophylaxis (CARP) trial, patients undergoing elective, open, abdominal aortic surgery for aortoiliac occlusive or aneurysmal disease at Veterans Administration hospitals were assessed for cardiac risk.⁴⁴ At an average of 2.7 years of follow-up after the aortoiliac procedure, there was no difference in outcome between those who underwent coronary revascularization prior to aortic surgery and those who did not (22% of patients who underwent coronary revascularization died, vs. 23% of those treated medically, $p = 0.92$). Only selected patients, therefore, require cardiac catheterization and occasional coronary angioplasty or bypass grafting before undergoing open aortic reconstruction, and these patients need to be stratified according to risk guidelines.⁴⁵

Pulmonary complications occur in 10% to 15% of patients after open aortoiliac repair,⁴⁶ and lung function should be assessed preoperatively only if clinical evaluation cannot determine that the patient is at his or her best achievable baseline pulmonary function and that airflow obstruction has not been optimally relieved. There is otherwise no indication for routine preoperative pulmonary function testing, as the American College of Physicians guidelines state that routine preoperative spirometry is not useful for predicting the risk of postoperative pulmonary complications.⁴⁷ Smokers who quit more than 4 weeks before surgery have significantly lower risk of respiratory complications and improved wound healing.⁴⁸

Choice of Revascularization Technique

A variety of surgical procedures, both endovascular and open, are available for revascularization in the patient with AIOD. Selection depends on a number of factors, including the pattern of the occlusive process, patient risk, surgeon experience, and patient preference.

Commonly used techniques include (a) catheter-based balloon dilation (angioplasty) with or without luminal stenting, (b) arterial reconstruction with an anatomically placed bypass prosthesis (aortofemoral or iliofemoral bypass), (c) arterial reconstruction with a remote (or extraanatomically placed) bypass prosthesis (axillofemoral or bifemoral, femorofemoral, thoracofemoral bypass), (d) aortoiliac endarterectomy, and (e) a hybrid approach encompassing a combination of endovascular and open procedures.

Catheter-based techniques are best suited for localized lesions of the common iliac arteries. However, it is currently being used as the main therapeutic modality for the majority of patients; it has essentially replaced endarterectomy procedures in patients with focal AIOD. Prosthetic aortofemoral bypass is the procedure of choice for most patients with advanced, extensive aortoiliac atherosclerosis and is still considered the “gold standard” for aortoiliac revascularization. Femorofemoral or iliofemoral bypass can be chosen in poor-risk patients with diffuse unilateral iliac disease, or with bilateral iliac involvement, when the stenosis in one of the iliac arteries can be appropriately treated by balloon angioplasty, with or without intraluminal stenting.

Axillofemoral or bifemoral bypass is reserved for the small subset of patients in whom standard aortic reconstruction is considered too risky, either for medical reasons (usually severe pulmonary or cardiac disease) or for technical reasons (e.g., aortic reoperations, multiple prior abdominal procedures with dense adhesions, prior abdominal irradiation, and prosthetic graft infection). The descending thoracic aorta can be considered as an alternative inflow source in the construction of a thoracofemoral bypass in a low-risk patient with a “hostile” abdomen.⁴⁹

Endovascular Surgical Management

5 Since the very first transarterial dilation procedures by Dotter, the development of balloon angioplasty by Gruntzig, and the deployment of intra-arterial stents by Palmaz, PTA has become the most commonly performed and, in some cases, the preferred therapy for iliac artery occlusive disease.^{50,51} Like open operative reconstruction, PTA, when properly selected, has a high rate of success owing to the large caliber and high rates of flow in the aortoiliac segment. The pattern of the occlusive process and patient comorbidities are primary considerations in selecting PTA as the mode of therapy. The best results are obtained with short, focal, stenotic lesions in the common iliac arteries (TASC A and B).⁵² Patients with severe atherosclerotic lesions, complex aortoiliac stenoses, or occlusions (TASC C or D) may also benefit more from endovascular approaches, with many series documenting excellent short-term success. Atheromatous embolism (blue toe syndrome) from an ulcerative plaque may be treated with placement of a stent to trap the debris, relieve the stenosis, and prevent recurrent embolism.

Description of Technique

Preprocedure planning sets the stage for a successful endovascular intervention. Although not always indicated, CTA or MRA delineates the location, extent, and degree of stenosis and associated calcification (Fig. 92-6A). Other considerations include the possible need for a concomitant femoral endarterectomy. When there is significant common femoral artery disease (>50% stenosis) along with iliac occlusive disease, a hybrid approach is preferred, where in addition to PTA, a femoral endarterectomy with patch angioplasty is performed. The endarterectomy should extend as high as possible under the inguinal ligament into the external iliac artery to facilitate stent deployment into the proximal endarterectomized segment and avoid its placement in the common femoral artery itself. A hydrophilic wire with an angled tip, usually a Glidewire (Terumo Interventional Systems, Somerset, NJ) and a straight or angled catheter for support are utilized to cross the stenosis or occlusion. Common iliac artery disease is treated through an ipsilateral retrograde approach if the external iliac is open. If the common iliac artery is occluded, bilateral punctures of the femoral arteries will be necessary to perform an aortography and to delineate the extent of obstruction (Fig. 92-6B). External iliac disease is usually approached with a contralateral antegrade approach across the aortic bifurcation. Crossing total occlusions may be challenging, and reentering the true lumen from the subintimal space can be difficult. If reentry cannot be achieved from the chosen point of vascular access (e.g., the ipsilateral common femoral), an attempt may be made from a new access site (e.g., contralateral common femoral or brachial). For more challenging cases, reentry devices such as the Outback (Cordis Corp., Bridgewater, NJ) or Pioneer (Medtronic, Fridley, MN) catheters may be used. Once the lesion is successfully crossed with a wire, the mode of intervention should then be considered. The typical balloon used for common iliac arteries is 8 to 10 mm, and for external iliac arteries 6 to 8 mm. The principal cause of balloon angioplasty failure is recoil of the atherosclerotic artery or a flow-limiting dissection. Stents serve as support to oppose the elastic recoil of the media and adventitia of the artery after angioplasty. They are also highly effective in sealing dissection planes within the atherosclerotic plaque resulting from the angioplasty procedure. Stents are also indicated in residual post-balloon stenosis (>30%), residual gradients (>10 mm Hg), ulcerative plaques that have a high risk of showering debris, and after recanalization of an occluded artery.

Self-expanding stents come precovered with a sheath and can be introduced into the lesion directly. Pulling back the sheath allows the compressed stent to assume its expanded form. Self-expanding stents may be more flexible and less likely to get crushed in the event they are deployed close to or past the inguinal ligament into the common femoral artery and are, therefore, used more frequently in the external iliac artery. With self-expanding stents, postdeployment balloon angioplasty is usually needed to achieve full expansion. These stents are usually chosen 10% to 15% larger than the intended lumen diameter; undersizing must be avoided as self-expanding stents cannot be dilated past their nominal diameter.

Balloon expandable stents are sometimes preferred to self-expanding stents in the common iliac artery, owing to their ease and precision of deployment, their better visibility under fluoroscopy, and the increased radial force of their design. These stents are usually introduced through a long sheath passed through the lesion to prevent dislodgment of the stent as it traverses the lesion. The sheath is pulled back once the stent is in satisfactory position, and the stent is deployed under fluoroscopic guidance. Balloon expandable stents are usually sized to the diameter of the normal adjacent artery. Slight undersizing of the stent can be easily managed by further dilating the stent, using a larger balloon.

The role of primary iliac artery stenting was addressed in the Dutch Iliac Stent Trial.⁵³ Primary angioplasty was compared to primary stenting. Stents were used in 43% of patients who underwent primary angioplasty because of poor results with dilatation alone. There was no difference between the groups at 2 years, with approximately 70% of both groups maintaining iliac artery patency. This result is in contrast to other studies that found that primary stenting for complex aortoiliac disease decreased complications and reduced overall long-term failure by up to 39%.^{54,55} Most interventional vascular specialists stent iliac lesions primarily.

Covered balloon-expandable (iCast, Atrium Medical Corp, Hudson, NH) and self-expanding stents (Viabahn, W.L. Gore and Associates, Flagstaff, AZ) have been introduced and are purported to offer a longer patency rate by controlling neointimal hyperplasia that may grow through the interstices of a noncovered stent, especially in TASC C and D lesions.^{56,57} Covered stents may also be useful for ulcerated plaques, because they are thought to reduce the chance of distal atheromatous embolism and for heavily calcified or tortuous iliac arteries that are more prone to rupture with balloon inflation.⁵⁸ Endovascular stent grafts, similar to those used in the treatment of abdominal aortic aneurysms, have

been evaluated for the treatment of AIOD.⁵⁹ In one series, the 4-year primary and secondary patency rates were 66% and 72%, respectively. Although these rates are inferior to conventional open reconstruction, they suggest that endovascular reconstruction affords a reasonable alternative when open procedures are high risk or contraindicated.

Intravascular ultrasound is a modality used during an intervention, rather than as an initial diagnostic tool. It is helpful in sizing iliac stenoses to choose the appropriate-size balloon and stent.³⁸

Lesions just above the aortic bifurcation are usually complex, exophytic, and calcific, and usually involve both common iliac arteries. Safe and effective intervention in this situation typically requires the use of two stents, one in each iliac artery, that partially project into the aorta so that they “kiss” in the distal aorta (Fig. 92-6C). Theoretically, treating only one common iliac artery orifice (i.e., the lesion is close to the aortic bifurcation) can result in plaque shifting during the angioplasty, causing a new obstruction in the contralateral lumen. Treating both sides simultaneously avoids this complication.

Complications of Endovascular Interventions

Access site complications are the most common. These include access site hematomas and retroperitoneal bleeding (4% to 17%), pseudoaneurysms (0.5% to 3%), arterial dissection (2% to 5%), and distal embolism (1% to 11%). In experienced hands, these complications are infrequent and can usually be remedied with ultrasound-guided therapy (compression or thrombin injection), intraluminal stenting, or thrombolytic therapy.⁶⁰ Contrast-induced nephropathy, however, is a particularly troubling complication, especially in patients with preexisting renal insufficiency.⁶¹ Low osmolality or isoosmolality agents should be used in patients with moderate renal insufficiency. Avoidance of volume depletion, non-steroidal anti-inflammatory drugs, and possibly volume expansion should be considered.⁶²

The most serious intraoperative complication is arterial rupture during angioplasty (0.5% to 3%).⁶⁰ This is seen as active extravasation on the postintervention angiogram. Treatment is quick passage and reinflation of the balloon to occlude the rupture site and maintain hemodynamic control and then either deployment of a covered stent across the rupture site or open repair in the operating room.

Outcome of Endovascular Interventions

Initial technical success is quite high, in the order of 98%, for TASC A and B lesions. TASC C and D lesions may not be as amenable to endovascular intervention. Surveillance with ABIs and possible duplex ultrasound play a major role in maintaining patency in these patients. The primary patency of iliac artery stenting is 70% at 5 years, but this can improve to 85% with close surveillance and reintervention as necessary (Table 92-2).^{60,63–65} Late failures are related to the initial extent of atherosclerosis and the diameter of the treated vessels.⁶⁶

Open Surgical Management

6 Aortobifemoral (or aortofemoral for short) bypass has been the standard open surgical procedure for treating AIOD for decades. Five-year patency rates are in excess of 95%, which is unmatched by any endovascular procedure.^{67,68} However, direct revascularization of the aortoiliac segment is currently reserved for patients with advanced (TASC C or D) occlusive disease, for whom the risk of surgery is acceptable and a durable long-term result is expected.

Description of the Aortofemoral Bypass Operation

Aortofemoral bypass remains the reference standard for reconstruction of advanced AIOD (Fig. 92-7).⁶⁹ The operation begins with bilateral groin incisions to expose the common, superficial, and deep femoral arteries. Starting the operation in the groins then moving to the abdomen minimizes the duration the abdomen is open. This limits fluid loss and hypothermia, and decreases the risk of graft infection. If the femoral arteries are severely atherosclerotic, the external iliac just above the inguinal ligament is often a soft, disease-free segment that is amenable to safe clamping. The profunda femoris (deep femoral) artery is a critical collateral pathway for the entire lower extremity. If disease is present at its origin, exposure beyond this segment with division of the overlying lateral circumflex femoral vein may be necessary for complete endarterectomy.

The abdominal aorta is usually exposed via a midline, transperitoneal, inframesocolic approach. The transverse colon is retracted cephalad, the ligament of Treitz taken down, and the duodenum (third and fourth portions) mobilized to the right. The left renal vein is identified in the retroperitoneum and serves as the most cephalad limit of exposure in most cases (0.3% of patients have a retroaortic left

renal vein).⁷⁰ The anterior surface of the aorta is then exposed from lower border of the left renal vein to just below the IMA. Numerous lymphatics are usually encountered in the para-aortic retroperitoneal space. These should be ligated to decrease the chances of a chyle leak. The left renal vein is mobilized if more proximal aortic control is needed; this is performed by ligating the adrenal, gonadal, and lumbar branches. It is generally unnecessary to divide the renal vein. Distal control of the aorta is dictated by the extent of disease. When exposing sites for distal control, the location of the hypogastric plexus and the presacral nerves, which course anterior to the aorta and travel caudally over the aortic bifurcation and origin of the left common iliac artery, needs to be kept in mind. Injury to these nerves can result in erectile dysfunction in men while injury to the sympathetic chain can cause retrograde ejaculation. Retroperitoneal tunnels are then developed between the exposed infrarenal aorta and the groins by means of blunt finger dissection. The tunnels are directed posterior to the ureters to avoid postoperative obstructive uropathy from entrapment of the ureter between the graft limb and the native iliac artery. A retroperitoneal approach to the aorta via a left flank incision is an accepted alternative, especially in those patients with “hostile” abdomens; however, it makes creation of the tunnel for the right limb of the bypass graft slightly more challenging.⁷¹

A bifurcated vascular prosthesis of appropriate size is selected, typically a presealed knitted Dacron or a polytetrafluoroethylene graft, and the patient is heparinized. With an occluding clamp below the renal arteries and another just above the IMA, the proximal anastomosis between the graft and the aorta is performed in either an end-to-end or end-to-side fashion. Though most vascular surgeons prefer an end-to-end anastomosis for technical simplicity, the end-to-side technique has been found to be just as good, depending on the pattern of occlusive lesions and need to perfuse patent hypogastric arteries.⁷² The proximal anastomosis is placed as close to the renal arteries as practical to prevent future compromise of the bypass resulting from progression of atherosclerosis in the remaining infrarenal cuff. The limbs of the prosthesis are then delivered through the retroperitoneal tunnels into the groins. The distal anastomoses are performed to the common femoral arteries and should be carried onto the profunda femoral arteries if there is any disease at the femoral bifurcation. Common femoral and profunda femoris origin endarterectomy may be needed and should be carried out prior to the anastomosis. Maintaining good outflow through the profunda femoris is very important as many of these patients have concomitant superficial femoral arterial disease, which may compromise long-term graft patency. In the rare patient with tissue loss secondary to multilevel disease (AIOD associated with an occluded superficial femoral artery and compromised deep femoral collaterals), a concomitant distal bypass (femoropopliteal–tibial) may also be required.

Endarterectomy

Endarterectomy was more commonly performed in the era before reliable vascular prosthetic conduits were available. The high success rates of angioplasty and stenting for the more limited disease patterns amenable to endarterectomy have rendered aortoiliac endarterectomy essentially obsolete in most current practices.

Table 92-2 Results of Endovascular Interventions

Procedure	Technical Success	5-yr Primary Patency	5-yr Secondary Patency	Mortality
Iliac angioplasty and stenting	85–100%	60–80%	80–98%	1–6%

reserved for patients with advanced aortoiliac disease who are poor surgical risks with a reduced life expectancy or those with a “hostile” abdomen.⁷⁴ For high-risk patients with diffuse advanced disease limited to one iliac artery, cross-femoral (or femoral artery-to-femoral artery) bypass or an iliofemoral bypass is a good option.⁷⁵

Outcomes

The excellent durability of aortofemoral bypass is related to the large caliber and high flow rates of the vessels involved. Results of direct surgical revascularization are listed in (Table 92-3). Aortofemoral bypass has excellent primary graft patency rates of approximately 85% to 95% at 5 years and 75% to 88% at 10 years. Factors associated with lower long-term patency of these grafts include female sex (in part due to smaller vessel size), multilevel arterial occlusive disease, and young age (<50 years) where premature and aggressive atherosclerosis is usually present.^{76,77} The most common cause of failure of surgical reconstructions is the progression of atherosclerosis or the development of anastomotic neointimal hyperplasia.⁷⁸ Axillofemoral grafts by comparison have patency rates of only 60% at 3 years. Femoral-femoral grafts are intermediate in performance with a 5-year patency of 50% to 60%.

Table 92-3 Results of Direct Surgical Revascularization

Procedure	5-yr Patency	Operative Mortality
Aortofemoral bypass	80–95%	2–4%
Femorofemoral bypass	50–60%	1–3%
Axillobifemoral bypass	30–50%	1–4%

Complications

As previously stated, aortofemoral grafting is considered the gold standard for the treatment of AIOD. Due to advancements in anesthesia and surgical critical care, aortofemoral bypass can be performed with perioperative mortality and morbidity below 5%, respectively⁶⁷ (Table 92-3). The perioperative morbidity and mortality for axillofemoral bypass is similar but is performed, in general, on a much higher risk population of patients.

Early Complications

- Postoperative cardiac events have decreased to less than 5%. This is due to diligent preoperative screening and following the excellent perioperative guidelines promoted by numerous professional societies including the use of aspirin, statins, and perioperative beta-blockers.
- Pulmonary complications are not infrequent, occurring in up to 7% of patients. Adequate pain control with epidural anesthesia to facilitate pulmonary toilet and avoiding volume overload can help reduce these complications.
- Atheroemboli can occur during the procedure, manifesting as end organ ischemia of the skin, pelvis, spinal cord, and bowel. Attention to detail during arterial clamping and flushing out the graft before unclamping can minimize this complication.
- Ischemic colitis and pelvic ischemia are rare and can be minimized by planning a procedure that maintains pelvic perfusion and blood flow to the IMA when collateral flow is insufficient to maintain left colon viability. Selective reimplantation of the IMA can be performed when poor IMA perfusion is anticipated or demonstrated. Ischemic colitis may require colectomy for treatment, but this is associated with a 50% mortality.
- Acute renal injury can result from either atheroembolism from aortic clamping close to the renal arteries or from corticomedullary renal shunting induced by the acute increase in afterload attendant with aortic clamping.
- Other possible complications include wound complications, particularly in the groin (lymphocele, lymphocutaneous fistula, wound infection), postoperative hemorrhage, erectile dysfunction in men, bowel injury, pancreatitis from retraction injury, and spinal cord ischemia. Wound complications can be particularly troublesome for axillofemoral and femoral-femoral bypasses because of the subcutaneous location of these prosthetic grafts.

Late Complications

- Graft thrombosis that is largely due to progression of native atherosclerotic disease either proximal or distal to the graft, or to anastomotic neointimal hyperplasia.

- Pseudoaneurysms from material fatigue, suture fracture, artery wall degeneration, or occult infection.
- Graft infections. A graft enteric fistula (most frequently to the third/fourth portions of the overlying duodenum) may present as a gastrointestinal bleed. Every gastrointestinal bleed in a patient with a history of aortofemoral bypass or other aortic reconstruction should be considered to be an aortoenteric fistula until proven otherwise.

Chapter 93

Peripheral Arterial Disease

William P. Robinson III

Key Points

- 1 Chronic obliterative atherosclerosis of the infrainguinal vessels is the most prevalent manifestation of peripheral arterial disease (PAD) encountered by the vascular surgeon.
 - 2 The major risk factors for the development of PAD include smoking, diabetes, advanced age, male gender, hypertension, dyslipidemia, and chronic kidney disease.
 - 3 PAD is a powerful risk factor for cardiovascular morbidity and mortality.
 - 4 The most common lesion seen below the inguinal ligament is that of a short-segment total occlusion of the superficial femoral artery.
 - 5 Typically half of patients proceeding to revascularization for arterial occlusive disease have significant coronary artery disease; even more have hypertension, and almost 80% are current or prior cigarette smokers.
 - 6 The diagnosis of infrainguinal occlusive disease is generally made based on patient symptomatology, physical examination, and noninvasive tests, such as ankle–brachial index (ABI), segmental pressure measurements, and pulse volume recordings.
 - 7 Percutaneous endovascular therapy is often applied as first-line therapy, particularly in patients with more limited extent of anatomic disease and/or high operative risk.
 - 8 Open surgical revascularization remains the gold standard for those patients with disabling claudication, ischemic rest pain, and ischemic ulceration or gangrene.
 - 9 Infrainguinal arterial bypass surgery remains the signature operation distinguishing vascular surgeons from other specialists involved in the treatment of peripheral vascular disease.
 - 10 Infrainguinal bypass surgery is best performed with autogenous vein conduit, preferably the ipsilateral greater saphenous vein if available.
 - 11 Many of the patients undergoing surgical reconstruction for critical limb ischemia (CLI) with tissue loss will require one or more adjunctive operative procedures for salvage of their foot.
-

1 The term “Peripheral Arterial Disease (PAD)” broadly denotes stenotic, occlusive, and aneurysmal diseases of the aorta and its branch arteries, exclusive of the coronary arteries. In common clinical usage, PAD, which is defined as an ankle–brachial index (ABI) < 0.9 , denotes atherosclerotic stenosis or occlusion of the arteries supplying the lower extremities.¹ Atherosclerotic occlusive disease of the aorta and iliac arteries is covered in [Chapter 92](#). This chapter will cover PAD located in the femoropopliteal and tibial (infrainguinal) arteries. PAD affects 12% of the U.S. adult population and almost 20% of U.S. adults older than age 70 years.^{1–3} PAD involving the lower extremities is the third leading overall cause of atherosclerotic morbidity worldwide after coronary artery disease and stroke.⁴ With the aging of the American population, the prevalence of lower extremity occlusive disease has steadily increased in recent decades. Not surprisingly, therefore, the clinical manifestations and complications of atherosclerosis are the most common therapeutic challenges encountered and treated by vascular surgeons.

The tendency for atherosclerotic lesions to develop at specific anatomic sites and follow recognizable patterns of progression was first appreciated in the late 1700s by the British anatomist and surgeon John Hunter. Considered one of the forefathers of vascular surgery, his dissections of atherosclerotic aortic bifurcations are preserved at the Hunterian museum in London and presage the disease process that Leriche would give his name to 150 years later.⁵ The modern era of surgical reconstruction for complex atherosclerotic occlusive disease began in earnest in 1947, when the Portuguese surgeon J. Cid dos Santos successfully endarterectomized a heavily diseased common femoral artery.⁶ Four years later, building on the pioneering work of Alexis Carrel, Kunlin would report the first long-segment vein

bypass in the lower extremity.^{7,8} It would be another 10 years before the initial efforts to extend vein grafting to the tibial level were described by McCaughan.⁹ The last three decades have seen tremendous advances in both the understanding of atherosclerosis biology and refinement in the techniques of infrainguinal surgical revascularization that have greatly improved surgeons ability to preserve limbs and improve quality of life in patients with femoropopliteal and tibial occlusive disease. Moreover, in the last two decades, advances in percutaneous treatment have revolutionized the treatment of infrainguinal occlusive disease. The concept of intravascular intervention was pioneered in the late 1960s by the radiologist Charles Dotter, and advanced greatly with the advent of the angioplasty balloon by Gruntzig in the early 1970s.^{10,11} Nevertheless, endovascular intervention for infrainguinal disease was not utilized significantly until the 1990s. The technology remains in rapid development and surrounded by ongoing controversy as to its proper role.

Although a diverse range of technical skill is required of the contemporary vascular and endovascular surgeon, it is worth noting that infrainguinal arterial bypass surgery remains the signature operation distinguishing vascular surgeons from other specialists involved in the treatment of PAD. This distinction stems primarily from the fact that the outcome of infrainguinal reconstruction is highly dependent on the judgment and technical skill of the surgeon, with the end result often being either successful limb salvage or major limb amputation. This chapter reviews the surgical and endovascular management of femoropopliteal and tibial arterial occlusive disease and details standard and advanced techniques underlying successful infrainguinal operative revascularization. Endovascular intervention is introduced, though a comprehensive review of endovascular techniques used to treat femoropopliteal and tibial occlusive disease is beyond the scope of the chapter.

INFRAINGUINAL ARTERIAL OCCLUSIVE DISEASE

Epidemiology and Risk Factors

Symptomatic PAD in the form of claudication affects more than 10 million Americans including 1% to 2% of those aged <50, 5% of those aged 50 to 70, and 10% of those aged >70. Of those aged >50 with PAD, 1% to 3% will have critical leg ischemia in the form of rest pain or gangrene.^{12,13} The incidence of CLI ranges from 220 to 1,000 new cases per year in a European or American population of 1 million people.¹⁴

2 The risk factors for infrainguinal occlusive disease are the same as those for the development of atherosclerosis in general and include age, male gender, hypertension, diabetes mellitus (DM), smoking, dyslipidemia, family history, and homocysteinemia. Smoking and diabetes are the most powerful risk factors. Smokers are at four times the risk of symptomatic PAD than nonsmokers while diabetics are more than three times more likely to develop symptomatic PAD in comparison to nondiabetics.¹⁴ The propensity for heavy smokers to develop superficial femoral artery disease and for diabetics to develop tibial disease should be noted. More recent evidence indicates that nonwhite ethnicity, inflammatory markers such as C-reactive protein, and perhaps chronic renal insufficiency (CRI) are also associated with an increased risk of PAD.¹⁵⁻¹⁷

Presentation and Natural History

3 Chronic obliterative atherosclerosis of the infrainguinal vessels is the most prevalent manifestation of PAD encountered by the vascular surgeon. Patients are classified into two broad categories depending upon their symptomatology: claudicants and those with critical limb ischemia (CLI). Claudication, the reproducible ischemic muscle pain resulting from inadequate oxygen delivery during exercise, is the cardinal presenting symptom. Natural history studies indicate patients with claudication have increased rates of cardiovascular mortality, but an overall low risk of limb loss.^{18,19} Seventy to eighty percent of patients with claudication demonstrate a stable pattern of disease throughout their lifetime or have improvement in their symptoms as a result of risk factor modification, whereas 20% to 30% undergo operation within 5 years as a result of disease progression. Claudication will progress to CLI in only 5% to 10% of patients over their lifetime. However, PAD leading to claudication is a marker of severe systemic atherosclerotic burden and increased cardiovascular morbidity and mortality. Twenty percent of chronic instance experience a nonfatal myocardial infarction or stroke and 10% to 15% died of cardiovascular-related mortality at 5 years.¹³ The annual rates of mortality and limb loss in patients with claudication are approximately 2% to 5% and 1%, respectively.^{13,20}

4 The most common atherosclerotic disease pattern encountered distal to the inguinal ligament is that

of a short-segment total occlusion of the superficial femoral artery. Isolated disease of this nature typically presents as calf muscle claudication. It is not uncommon, however, for patients with significant single-level lesions, even those with long-segment arterial occlusions, in the superficial femoral artery or more distal arterial beds to be only minimally symptomatic or even asymptomatic. While this can sometimes be the result of exercise limitations imposed by concomitant coronary arterial disease or other physiologic impairments such as lung disease or arthritis, it is more often a result of compensatory collateral flow. Collateral perfusion from the profunda femoral artery around a heavily diseased or occluded superficial femoral artery frequently reconstitutes the distal superficial femoral artery or popliteal artery with enough well-perfused arterial blood to ensure sufficient resting tissue perfusion. Similarly, the rich network of geniculate collaterals can sometimes compensate for a diseased popliteal arterial segment to a sufficient degree to prevent rest pain or overt tissue loss, but will usually prove insufficient to meet the increased metabolic demands of ambulation and forestall claudication.

CLI, which must be differentiated from acute limb ischemia, is the most severe form of PAD and refers to the presence of either rest pain or tissue loss in the lower limb. Rest pain occurs when blood flow is inadequate to meet resting metabolic requirements. In the lower extremity, ischemic rest pain is localized to the foot, frequently in the metatarsals or the instep, and should be easily distinguishable from benign muscle cramps in the calf commonly seen in older patients. Patients with rest pain are often awakened by severe discomfort in the forefoot and hang the affected extremity over the edge of the bed for temporary symptomatic relief. Trophic changes, such as muscle wasting, thinning of skin, thickening of nails, and hair loss are frequently also seen in the distal affected limb. Rest pain is an ominous symptom and usually requires revascularization given the tendency for progression to tissue loss. Ischemia ulcerations usually begin as small, dry ulcers of the toes or heel area, and progress to frankly gangrenous changes of the forefoot or heel with greater degrees of arterial insufficiency (Fig. 93-1). Patients with diabetes or renal failure are more susceptible to the development of ischemic pedal ulcers. Disease progression can be very rapid, as up to 50% of patients with CLI are asymptomatic 6 months before onset of pain or ulceration.²¹ Such progressive disease, affecting multiple levels of the peripheral vasculature tree, is more frequently encountered in the elderly.

The natural history of CLI is dismal as these patients are generally of advanced age and possess significant comorbidities contributing to their advanced limb ischemia. Overall, approximately 25% of patients with CLI will die at 1 year, 30% will undergo major amputation, and 45% will be alive with two limbs.^{13,14} The rate of amputation is 10 times higher in diabetics than nondiabetics and 5- and 10-year mortality in patients with CLI have been reported to be 60% and 85%, respectively.²¹ CLI mandates revascularization for limb salvage when feasible, as limb salvage with medical therapy and wound care is virtually futile; success rates for rest pain and tissue loss have been reported to be as low as 27% and 5%, respectively.²¹

Several identifiable patterns of infrainguinal PAD are well recognized. It is important to note that symptoms and signs of ischemia generally involve the limb one level distal to the level of hemodynamically significant disease. Patients with an extensive history of cigarette smoking typically have lesions limited to the superficial femoral artery and corresponding symptoms of calf claudication (Fig. 93-2). Patients with rest pain or ischemic tissue loss typically manifest more extensive involvement of the femoral, popliteal, or tibial arteries than patients with claudication. Those with tissue loss also more commonly have multilevel disease involving the femoropopliteal system in combination with occlusive disease of the aortoiliac vessels or the infrageniculate runoff.²² Diabetes often targets the tibial vessels, and patients may present with frank tissue necrosis in the presence of a palpable popliteal pulse and no prior history of claudication. Alternatively, the so-called “blue toe syndrome” is a situation in which atherosclerotic debris breaks free from a more proximal source, for example, an aortoiliac or femoropopliteal plaque or a thrombus-lined aneurysm, and embolizes to the distal vessels.²³ Wire manipulation during coronary or peripheral angiographic procedures and crossclamping across a calcific aortic plaque during cardiac surgery are common sources of such emboli. The terminal target of the microembolic particles, whether cholesterol crystals, calcified plaque, and thrombus or platelet aggregates, is typically the small vessels of the toes and heel.

Figure 93-1. A–C: Examples of digital ischemic ulcerations resulting from progressive arterial insufficiency.

Figure 93-2. Long-segment total occlusion of superficial femoral artery in a patient with a long history of cigarette smoking and severe claudication. Proximal sfa occlusion is demonstrated (A), followed by wire traversal of the occlusion (B), which will allow endovascular treatment of the occluded segment of the sfa proximal to reconstitution of the above-knee popliteal artery (C).

A particularly virulent form of atherosclerotic arterial disease is often found in young female smokers.^{24,25} Radiographic imaging in this subset of patients typically reveals atretic, narrowed vasculature with diffusely calcific atherosclerotic changes. Such patients invariably have an extensive smoking history, with or without other typical risk factors for atherosclerosis. Given the diminutive size of the inflow and outflow vessels, the durability of endovascular intervention is generally inferior in these patients, particularly in the face of continued cigarette use.

5 Typically half of patients proceeding to surgery for arterial occlusive disease have significant

coronary artery disease, even more have hypertension, and almost 80% are current or prior cigarette smokers.^{26,27} The low mortality and morbidity associated with operative intervention in recent years are in large part a result of advances in the management of concomitant coronary disease. Specifically, the importance and benefit of better preoperative identification of patients in need of initial coronary revascularization, awareness of the benefit of waiting an interval period following coronary stenting prior to proceeding with major noncoronary vascular surgery, improved perioperative pharmacologic management of patients with impaired myocardium, and more focused efforts to tailor operative and postoperative fluid administration to the individual patient's myocardial reserve are all well recognized.^{28,29} Appropriate beta blockade and the use of statins have been shown to reduce cardiovascular events and improve survival after inpatients undergoing vascular surgery, including infrainguinal bypass.^{30,31} General advances in postoperative management, including pulmonary care, infection control, and blood product utilization, have further contributed to the progress seen.

Diagnosis

6 The diagnosis of infrainguinal occlusive disease is generally based on patient symptomatology, physical examination, and noninvasive tests, such as segmental pressure measurements and pulse volume recordings. Accurate history-taking and physical examination are crucial to clarifying the diagnosis and guiding a treatment management aimed at maximizing symptom relief and limb preservation. Intermittent claudication (IC) indicative of infrainguinal occlusive disease is typically a cramping, aching discomfort consistently reproducible at a given distance and relieved soon after cessation of ambulation. This must be differentiated from lower extremity pain secondary to nerve root compression or spinal stenosis which, in contradistinction to vasculogenic pain, often develops when patients maintain a stationary standing posture. Vasculogenic claudication must also be distinguished from venous claudication, hip and ankle arthritis, symptomatic Baker cyst, and chronic compartment syndrome. IC patients with isolated infrainguinal disease will likely have palpable femoral pulses but diminished popliteal and/or pedal pulses.

As is true with claudication, ischemic rest pain must be carefully distinguished from other sources of pain in the elderly population, most commonly arthralgia and neuropathy. Although tissue necrosis and gangrene are usually self-evident when caused by critical ischemia, similar lesions associated with venous stasis, severe anemia, decubitus ulcers, and diabetic neuropathy must be excluded.

Noninvasive physiologic arterial testing allows confirmation of infrainguinal occlusive disease when it is suspected based upon history and physical examination. Measurement of the ABI is the most useful diagnostic adjunct. A properly performed ABI in a claudicant without significant evidence for vascular calcification would be expected to be between 0.5 and 0.9. Ischemic rest pain generally occurs at ABI 0.4 to 0.5, whereas an ABI less than 0.4 is generally associated with tissue loss. Segmental pressure measurements at the level of the upper thigh, lower thigh, upper calf, ankle, and metatarsal level also aid in localizing the level of hemodynamically significant disease. A drop in pressure greater than 20 mm Hg between levels indicates a hemodynamically significant stenosis in the intervening arterial vasculature. In patients with DM or CRI leading to extensive vascular calcification, the ABI will often be erroneously elevated due to medial calcinosis and subsequent noncompressibility of the vessels. In such circumstances, pulse volume recordings, which ascertain the volume of blood flowing into segment of the limb, remain a reliable indicator of perfusion to the various levels of the lower extremity. Measurement of toe pressures also effectively quantitates distal perfusion as the digital arteries are generally spared of calcium which inhibits compressibility. A toe-brachial index less than 0.7 is considered abnormal. Absolute toe pressure less than 30 to 50 mm Hg generally indicates severe lower extremity occlusive disease with inadequate perfusion to heal tissue loss, particularly in diabetics.¹⁴

Further anatomic mapping is warranted only after the diagnosis of hemodynamically significant infrainguinal disease has been made based upon physical examination and noninvasive testing and the decision to pursue intervention has been made. The goal of anatomic imaging is to determine if adequate revascularization is anatomically feasible and to delineate the options for both endovascular therapy and open surgical revascularization. Duplex ultrasonography, magnetic resonance angiography (MRA), and computed tomographic angiography (CTA) are increasingly being utilized as first-line modalities in planning the optimal revascularization approach, and have supplanted contrast angiography as the initial imaging study of choice in many centers.³² Nevertheless, due to inherent limitations with each of these techniques, digital subtraction angiography remains the gold-standard technique for imaging of the vascular tree prior to intervention.³³

Although a growing literature supports the use of duplex scanning as a stand-alone preoperative

mapping modality,³¹ this use requires a highly dedicated vascular laboratory and to date has not gained wide acceptance. CTA is increasingly being utilized as a preoperative road-mapping technique in institutions able to provide high-quality three-dimensional reconstructions. MRA is also particularly useful as a noninvasive screening test to determine the suitability for percutaneous therapy, as advances have solved many of the technical limitations of earlier studies (Fig. 93.3). Should a lesion amenable to percutaneous therapy be identified, angiography is then pursued. Alternatively, in some instances of femoropopliteal reconstruction, operative planning may be based solely on MRA scanning if high-quality time of flight and gadolinium-enhanced images are obtained.^{34–36} In many cases, however, surgeons are reluctant to proceed to surgery without the confirmation of anatomy afforded by standard contrast angiography. This reluctance is particularly true if the distal target is at the tibial or pedal level, where anatomic detail provided by CTA and MRA remains more limited.³⁷

When digital subtraction angiography is undertaken for preoperative planning, a retrograde femoral approach is typically utilized from the contralateral limb. In general, a catheter is placed in the infrarenal aorta to perform aortography and iliac angiography. If there is no aortoiliac disease which precludes catheter traversal, the wire and catheter are utilized to go “up and over” the aortic bifurcation to place the catheter in the common femoral artery of the affected limb. Lower extremity digital subtraction angiography is then carried out. Selective catheterization of the affected limb via “up and over” approach allows contrast volume to be minimized. It also allows the surgeon or interventionalist to proceed immediately with infrainguinal endovascular intervention through a single vascular access should endovascular therapy be the preferred treatment based on the patient’s presentation and infrainguinal anatomy defined in the angiogram.³³ In patients in whom noninvasive imaging indicates a widely patent common femoral and proximal superficial femoral artery and body habitus is not prohibitive, an antegrade approach can serve as useful alternative. In ambiguous lesions or when iodinated contrast must be minimized, pull-back pressure measurements, both before and after the administration of a systemic vasodilator such as papaverine or nitroglycerine or the application of a tourniquet to induce reactive hyperemia, can be useful in documenting the hemodynamic significance of a particular stenotic zone.³⁸ The utilization of gadolinium or carbon dioxide as contrast agents in patients with compromised renal function, although perhaps less effective in the periphery than in the aortoiliac vasculature, can minimize or eliminate the nephrotoxic effects associated with standard iodinated contrast medium.^{39,40}

Figure 93-3. Magnetic resonance angiogram identifying patent inflow vessels (A), short-segment occlusion of right superficial femoral artery (B), and patent popliteal and tibial vessels (C and D), a lesion amenable to attempt at percutaneous therapy.

Medical Treatment

Risk factor modification remains a cornerstone of the management of lower extremity occlusive disease. Smoking cessation has been shown to reduce the risk of disease progression, amputation, cardiovascular mortality, and may lead to symptom relief in some patients. Smoking cessation has been best achieved with repeated physician assistance, group counseling, nicotine replacement or nicotinic receptor agonists, and antidepressant drug therapy in some patients. Weight and blood pressure reduction and aggressive efforts at lipid control should be addressed with every patient with atherosclerotic disease. Lipid-lowering therapy involves dietary modifications first and utilization of hydroxymethylglutaryl-coenzyme A-reductase inhibitors (“statins”) to lower LDL cholesterol and fibrates or niacin to raise HDL cholesterol. Patients with lower extremity occlusive disease should have a goal LDL cholesterol of <70 mg/dL.¹³ Statin therapy also has benefits in patients with PAD which are independent of their effect on lipid reduction. Statins stabilize atherosclerotic plaque and reduce vascular inflammation. Statin therapy has been shown to reduce cardiovascular events in patients with PAD.^{41,42} In addition, statin therapy is associated with improved 1-year survival in patients undergoing lower extremity bypass for CLI.³¹ Patients with diabetes should have aggressive control of blood glucose toward a goal hemoglobin A1C of <7%. Antiplatelet therapy in the form of either aspirin or clopidogrel is a critically important element of the treatment of established occlusive disease, given its documented ability to prevent thrombosis and embolization and possibly even to arrest the progression of atherosclerosis.⁴³ Aspirin and clopidogrel have both been shown to reduce cardiovascular morbidity and mortality in patients

with PAD.^{44,45}

Strong evidence exists supporting the benefit of a supervised, structured walking program in increasing the walking distance of patients with claudication.⁴⁶ The benefit of walking outside of a structured regimen with close follow-up is more debatable.⁴⁷ Nevertheless, patients should be encouraged to “walk through” the onset of lower extremity pain, resting intermittently as required. Overall, pharmacotherapy has not had a significant impact on relieving symptoms of infrainguinal occlusive disease. There is some evidence to suggest cilastazol, a phosphodiesterase inhibitor, improves walking distance and quality of life.^{48,49} While early studies showed that pentoxifylline, a rheologic agent, had beneficial effects on walking distance, later studies have questioned its clinical benefit.^{50,51} Similarly, although older studies suggested that prostanooids improved healing of ischemic ulcers, the current evidence does not support the utility of any systemic drug for the relief of ischemic rest pain or the treatment of ischemic ulcerations.⁵²⁻⁵⁴

Indications for Revascularization

The two major indications for the intervention of infrainguinal arterial occlusive disease are lifestyle-limiting claudication and CLI. Less common indications for infrainguinal arterial reconstruction include trauma-related vessel disruption, popliteal artery entrapment syndrome, and femoropopliteal arterial aneurysm with thromboembolism. Infrainguinal revascularization for the treatment of peripheral vascular occlusive disease has been increasingly successful for both long-term palliation of IC and for the preservation of limbs threatened by critical ischemia.

Critical ischemia is associated with inevitable amputation for most patients unless revascularization is undertaken. Although there are certainly cases in which primary amputation represents the safest and most advisable solution in the face of irreversible ischemia, particularly in nonambulatory patients or in cases in which extensive infection or tissue necrosis is present, an attempt at revascularization is generally indicated when a limb is threatened by severe ischemia. However, given the morbidity and mortality associated with CLI, it is paramount to tailor therapy to an individual’s overall medical condition and life expectancy as well as the patient’s goals of therapy. In the often frail CLI population, postoperative outcomes are most strongly impacted by patients’ preoperative medical condition and functional status.⁵⁵ Nevertheless, improvements in endovascular technology and techniques as well as perioperative management and surgical technique have allowed progressively more distal revascularizations to be successfully completed in an older, sicker, and challenging patient population. In general, high limb salvage (80% to 90%) rates may be anticipated for patients with critical ischemia at institutions devoted to peripheral bypass surgery.⁵⁶⁻⁵⁸ In addition, occlusive disease of the tibial vessels, once thought to be the exclusive domain of operative bypass, is increasingly being treated percutaneously.⁵⁹ Though the long-term durability of various endovascular revascularization approaches is limited, similar rates of limb salvage from 1 to 3 years have been demonstrated.⁵⁹⁻⁶¹

Claudication is a relative indication for intervention given the natural history of the disease, and it remains a subjective assessment on the part of both patient and surgeon as to the relative degree of disability a particular level of claudication pain represents. For example, two-block claudication in a younger patient whose livelihood depends on walking tolerance constitutes a more significant disability than the same degree of claudication in an older, retired individual able to attend to his or her daily affairs without significant consequence. Thus, proximal above-knee surgical reconstruction in a patient with disabling claudication and a patent popliteal artery with intact runoff may be justified in view of its minimal operative mortality, excellent long-term palliation, and absence of added risk of limb loss beyond that expected from the natural history of the disease process. Classically, it has been thought that the benign natural history of claudication does not warrant aggressive femorotibial reconstruction in patients with diffuse superficial femoropopliteal and tibioperoneal disease, though reconstruction will often provide symptomatic benefit and can be considered in a good-risk patient.⁶²

In recent years, the low morbidity of endovascular revascularization in combination with patient desire for intervention seems to have lowered the threshold for offering catheter-based revascularization for claudication. Patients once considered most appropriate for risk factor modification, exercise therapy, and medical treatment are now increasingly being offered percutaneous revascularization.^{63,64} Nevertheless, endovascular revascularization is not without risk and is at present of limited durability. It is therefore prudent to follow the classical surgical axiom that because most patients with claudication remain stable for years, it is important to allow sufficient time for collaterals to develop and enlarge; some patients may improve to such an extent that intervention proves unnecessary.¹⁹

Approach to Revascularization

The last two decades have seen increasing utilization of endovascular revascularization of infrainguinal occlusive disease.⁶⁴ In this light, it cannot be overemphasized that symptom status and not anatomic findings should serve as the basis for revascularization. Once the decision to intervene has been made, a variety of factors should be considered in choosing whether to proceed with an endovascular, surgical, or combined (hybrid) approach. The goals and outcomes of revascularization should be considered in the context of the individual patient's comorbidities, operative risk and overall life-expectancy, the extent of the occlusive disease present, and the expected durability of the procedure.

Anatomic variables appear to be the key determinant of the success and durability of endovascular therapy. With the promulgation of endovascular therapy has arisen, the need to classify the anatomic severity of disease in order to guide potential therapy and compare outcomes between various modes of revascularization. The Trans-Atlantic Intersociety Consensus Document on Management of Peripheral Arterial Disease (TASC) was published as the result of a multidisciplinary collaboration between key medical and surgical vascular societies in 2000 and an abbreviated update was published in 2007.^{14,65} This document classified infrainguinal occlusive lesions into classes A, B, C, and D based upon the location of the lesion and the number, length, and severity of the stenoses and/or occlusions present. Their recommendations, which reflect current practice to a variable extent, include initial endovascular treatment for TASC A lesions, primary surgical treatment for TASC D lesions, and individualized tailoring of treatment for TASC B and C lesions depending upon endovascular suitability and surgical risk. While a complete description of this classification schema is beyond the scope of this chapter, a few general principles are worth noting. The patency of endovascular revascularization decreases the more distal the disease and is less in patients with stenoses that are multiple, longer, and more severe.^{14,59,66} On the other hand, the success of open bypass surgery is largely dependent on the quality conduit.^{67,68} Sustained hemodynamic improvement in the affected limb is the measure of effective revascularization and the goal of therapy. Neither “endovascular first” nor “bypass first” approach can be applied to all patients. Selection of the optimal revascularization strategy, at least in CLI, involves assessment of life expectancy, surgical risk, the severity of tissue loss in the limb, the anatomic pattern of disease, and the quality of vein available as a conduit for bypass. The complexity of decision-making emphasizes the importance not only of interventional expertise, but of thorough training in vascular disease and comprehensive experience in the care of vascular patients.⁶⁹

Figure 93-4. Angiogram of the right superficial femoral artery demonstrating short-segment occlusion and more diffuse stenosis in Hunter canal (A), which was treated with angioplasty and self-expanding bare metal stent placement (B).

Endovascular Therapy

A marked increase in the number and versatility of available balloons, stents, and other devices has helped to fuel the increasing application of percutaneous technology. While a complete description of endovascular treatment options and outcomes is beyond the scope of this chapter, a brief introduction is

necessary. Percutaneous vascular intervention is generally performed under local anesthesia with minimal intravenous sedation as either a day surgical procedure or involving an overnight admission. Percutaneous vascular intervention first involves wires traversal of hemodynamically significant stenosis or occlusions in the arterial tree. Dilatation of the lesion with percutaneous transluminal angioplasty (PTA), with or without stenting, or obliteration of the lesion via atherectomy or other modalities is utilized to reestablish blood flow through the diseased segment (Fig. 93-4). For interventions on the femoropopliteal and tibial arteries, retrograde contralateral femoral access allows angiography of the affected limb and establishment of a stable treatment platform via an “up and over” approach across the aortic bifurcation. Ipsilateral antegrade femoral access can also be utilized. More recently, retrograde ipsilateral pedal and tibial access has been described to allow wire traversal and endovascular treatment of disease not amenable to the standard antegrade approach.⁷⁰

Periprocedural outcomes with endovascular therapy are excellent. Technical success, which is generally defined as the presence of antegrade flow through the tree to lesion with less than 30% residual stenosis at the conclusion of the procedure, is reported at 80% to 95% for both femoropopliteal and infrapopliteal procedures.^{59,71,72} Associated overall morbidity in recent reports ranges between 8% and 17% while mortality is low at approximately 0.2%. Contrast-induced nephropathy remains a common complication. With the development of hypoosmolar and isoosmolar contrast agents; the overall incidence is approximately 8%, whereas the rate of acute renal failure requiring dialysis is less than 1%.^{72–74} Higher rates are found in patients with pre-existing renal failure and diabetes.^{75,76}

Substantial morbidity can result from access-site complications, predominantly pseudoaneurysms, groin hematomas, and arteriovenous fistulas (AVFs), which occur in 1% to 4% of patients.^{72,77} Most of them can be managed conservatively, with close observation, serial hematocrit checks, and fluid and blood product replacement. Surgery is reserved for those patients with ongoing bleeding effecting hemodynamic instability or distal ischemia, or pseudoaneurysms or AVFs that fail to resolve on serial ultrasound imaging with several weeks of careful observation. Stable pseudoaneurysms in patients without coagulopathy can also be managed with ultrasound-guided compression therapy or ultrasound-guided thrombin injection into the pseudoaneurysm sac to induce thrombosis.⁷⁸ Infection related to the placement of newer percutaneous closure devices utilized for puncture site control typically present several weeks to months after the percutaneous procedure. Rarely, maldeployment of these devices can lead to embolic or thrombotic sequelae causing compromise of distal flow.⁷⁹

Reports indicate that endovascular therapy has good short-term efficacy for femoropopliteal disease (Table 93-1). In claudicants, PTA for femoropopliteal lesions has generally yielded 1-year patency of approximately 77% and 65% for stenoses and occlusions, respectively.^{66,80} In patients with CLI, PTA for femoropopliteal lesions has yielded 1-year primary patency of 60% and 40% for stenoses and occlusions, respectively.⁸⁰ Review of the literature does not provide compelling evidence that stent placement improves the results of all femoropopliteal PTA.⁶⁰ Many practitioners thus utilize stents selectively for failure of PTA (defined as greater than 30% residual stenosis or flow limiting dissection) in femoropopliteal lesions. However, there is strong evidence, including two randomized trials, that primary self-expanding stent placement yields higher short-term patency than PTA and/or provisional stenting for more advanced femoropopliteal lesions.^{80–82} Primary self-expanding stent placement is therefore preferred over angioplasty alone for femoropopliteal occlusions and long-segment lesions by most surgeons and interventionalists. Infrapopliteal disease appears less amenable to endovascular therapy (Fig. 93-5). Primary patency is generally reported at 45% to 55% at 1 year.^{59,83} Patency does not appear to be improved by stenting in the infrapopliteal segment.^{84,85}

RESULTS

Table 93-1 Patency of Femoropopliteal Angioplasty and Stenting^a

	1-year % Patency (Range)	3-year % Patency (Range)	5-year % Patency (Range)
PTA: stenosis	77 (78–80)	61 (55–68)	55 (52–62)
PTA: occlusion	65 (55–71)	48 (40–55)	42 (33–51)
PTA+stent: stenosis	75 (73–79)	66 (64–70)	
PTA+stent: occlusion	73 (69–75)	64 (59–67)	

^aAdapted from Norgren et al. Inter-society Consensus for the Management of Peripheral Arterial Disease (TASC II).¹⁴

Lack of durability has been the Achilles heel of infrainguinal endovascular intervention. Three-year

patency after PTA has generally been reported to be 43% to 61% and 30% to 48% for femoropopliteal stenoses and occlusions, respectively.⁸⁰ Five-year patency data are seldom reported but have been generally reported to be between 26% and 45% after PTA for femoropopliteal lesions.¹⁴

There is a scarcity of high-level data comparing PTA and bypass surgery for infrainguinal occlusive disease. Heterogeneous study populations and the lack of standardized methodology and endpoints have limited the ability to compare the effectiveness of endovascular surgical therapy.⁸⁶ In addition, there have been only four randomized trials comparing angioplasty and lower extremity bypass surgery and these have included a heterogeneous group of patients, measured different outcomes, and generally included limited anatomic detail.^{87–90} Pooled analysis of these trials demonstrates that surgical bypass generally had superior patency to PTA at 1 year, but there were no differences in progression to amputation. The BASIL (Bypass vs. angioplasty in severe leg ischemia) trial which randomized 452 patients with “severe limb ischemia” to a “bypass first” or “balloon angioplasty” first strategy is the most widely cited trial. There was no difference in the primary endpoint of amputation-free survival at 6 months, although a “surgery-first” strategy was associated with greater cost and morbidity.⁸⁷ It is necessary to note that the endovascular arm of this trial did not include adjunctive procedures such as stenting which are now frequently utilized in current day practice. Upon long-term follow-up of at least 3 years and more than 5 years in the majority of patients, bypass was associated with improved overall survival and a strong trend toward improved amputation-free survival in patients who survived at least 2 years. In addition, most balloon angioplasty patients ultimately required bypass surgery. Bypass after failed balloon angioplasty had significantly worse patency than that of primary bypass.⁹¹ This finding corroborated other reports demonstrating that surgical bypass after failed endovascular treatment is inferior to primary bypass, indicating that a universal “endovascular first” approach may not be appropriate as failed endovascular intervention may “burn bridges” for surgical revascularization. Careful consideration must be given to the best initial therapy for infrainguinal occlusive disease.⁹²

Figure 93-5. Angiogram of the tibial arteries showing diffuse anterior tibial artery high-grade stenosis (A) which was treated with long-segment balloon angioplasty, (B) completion angiogram showed patent anterior tibial artery with no significant residual stenosis (C).

7 8 For patients with favorable anatomy and significant operative risk, and for the treatment of claudication in general, percutaneous therapy has assumed a primary initial role. When medical therapy or percutaneous treatment has proven inadequate, open surgical revascularization remains the gold standard for those patients with disabling claudication. Furthermore, until the efficacy and durability of infrainguinal percutaneous intervention is better defined, surgical revascularization remains the gold standard for any patient with CLI, especially those with extensive tissue loss. The relative roles of surgical and percutaneous intervention are actively being refined. It nevertheless appears that the rising popularity and success of femoral and tibial wire-based interventions may be reducing the volume, or ultimately just delaying the timing of, subsequent infrainguinal reconstructive surgery. Furthermore, many patients are best treated with a combination of percutaneous and open surgical therapy, often in a

single procedure (hybrid procedure). In many instances, endovascular and open surgical revascularization are thus complementary modes of therapy.

Operative Management

9 Successful infrainguinal arterial bypass requires sound planning as well as technical expertise. As such, it remains the signature operation which distinguishes vascular surgeons from other specialists involved in the treatment of PAD. Successful infrainguinal bypass grafting requires adequate arterial inflow. While aortobifemoral, femorofemoral, and axillofemoral bypass grafting remain routinely performed inflow procedures, aortoiliac angioplasty and stenting are increasingly becoming the preliminary procedures performed to attain sufficient inflow prior to construction of a more distal bypass graft. At times, the necessity of improving the inflow to support an infrainguinal graft is determined intraoperatively, either by direct visual assessment of the arterial flow at the desired donor site or by comparison of a transduced pressure tracing from the donor site with that of a systemic pressure tracing, typically obtained from a radial arterial line. Of equal importance to the outcome of any infrainguinal graft is target vessel selection. In general, the target vessel should be the least diseased artery that is the dominant supply to the foot. If tissue necrosis is present, restoration of pulsatile flow to the foot is often required to obtain full and sustained wound healing.

Infrainguinal surgical bypass can be performed under general anesthesia, or in the appropriate patient, under regional, spinal, or epidural anesthesia. In cases involving multiple sites of dissection, such as those necessitating more tedious arm vein or lesser saphenous vein harvesting, the procedures are particularly amenable to a two-team approach, with the time saved having direct benefit in minimizing the total anesthetic load and physiologic insult. The patient is sterilely prepped and draped from the midabdomen down to the foot. It is our practice to work from proximal to distal, first exploring the inflow artery and exposing the venous conduit. We then explore the site proposed for the distal anastomosis, as high-quality preoperative imaging has already defined a suitable target vessel.

For patients with superficial femoral artery disease, the initial dissection is most commonly at the level of the common femoral artery. This vessel is exposed through a longitudinal or oblique incision centered directly over the femoral pulse. Lymphatic tissue overlying the femoral vessels is best ligated and divided to prevent the postoperative development of lymph fistulas or lymphoceles. The severity of any concomitant common femoral and profunda femoral disease and the level of reconstruction planned dictate the extent of exposure of the femoral vessels. In most instances, the dissection extends from the inguinal ligament to the common femoral artery bifurcation, where the origins of the superficial and profunda femoral arteries are individually isolated.

Figure 93-6. In the setting of orificial profunda femoral artery disease, extending the common femoral arteriotomy into the origin of the profunda and performing a profundaplasty will maximize profunda flow in the event of graft thrombosis.

If a profundaplasty is required, the dissection is extended distally along a sufficient length of the profunda femoral artery to attain an endpoint suitable for clamping and sewing (Fig. 93-6). Similarly, the inguinal ligament can be partially divided to facilitate access to the distal external iliac artery in cases in which a more extensive proximal endarterectomy is necessary. In these circumstances, it is customary to close the endarterectomized bed with a vein, bovine pericardial or Dacron patch, onto which the proximal anastomosis can subsequently be attached.⁹³ In patients with a hostile groin crease

from prior surgery or radiation therapy or in obese, diabetic patients with an intertriginous rash at the inguinal crease, meticulous skin preparation, close attention to draping, careful surgical technique, and judicious use of a short course of intravenous antibiotic therapy help minimize the chances of a postoperative wound or graft infection.

If all or part of the superficial femoral artery is spared of significant atherosclerotic involvement, the proximal anastomosis can be moved distally as dictated by the particular anatomic pattern of disease, and a so-called “distal origin graft” can be fashioned (Fig. 93-7).⁹⁴ This situation is particularly applicable to the diabetic population, in whom infrapopliteal disease is the rule and sparing of the superficial femoral and popliteal arteries is not uncommon. It is also utilized in situations in which conduit is sparse, and a moderately diseased proximal vessel is accepted as an inflow source for a more distal origin bypass graft in the interests of performing a fully autologous vein graft rather than utilizing prosthetic material. An increasingly popular approach when only limited conduit is available is to combine, either concurrently in the operating room or as a staged preoperative procedure, catheter-based treatment of the superficial femoral or popliteal artery inflow with more distal bypass.⁹⁵

The above-knee popliteal vessel is easily exposed through a medial thigh incision, with subsequent posterolateral retraction of the sartorius muscle. The popliteal artery with its accompanying vein and nerve is found just posterior to the femur. The vessel is palpated to determine the presence of atherosclerotic plaque, which will guide the extent of dissection and the optimal bypass target site. The below-knee popliteal artery is also exposed through a medial incision in the proximal calf (Fig. 93-8). If the saphenous vein is to be harvested, the incision is made directly over the vein to minimize the creation of devascularized skin flaps. With the exposed vein carefully protected, the incision is carried through the deep muscular fascia and the medial head of the gastrocnemius is reflected posterolaterally to expose the below-knee popliteal fossa. The distal popliteal artery is then dissected free from the adjacent tibial nerve posteriorly and popliteal vein medially. If the distal target is the tibioperoneal trunk, the dissection is continued along the anteromedial surface of the distal popliteal artery after dividing the origin of the soleus muscle from the tibia (Fig. 93-9). In instances in which the below-knee popliteal artery has previously been exposed or where sepsis is involved, a lateral approach with excision of a segment of proximal fibula is a useful alternative approach to the below-knee popliteal artery.

Figure 93-7. Arteriogram indicating preservation of the superficial femoral artery and popliteal arteries (A,B,C) with mid-calf occlusions of all three infrageniculate vessels (D), with reconstitution of the dorsalis pedis artery in the foot (E). This anatomic pattern of disease is amenable to “distal origin” vein grafting from the below-knee popliteal or proximal posterior tibial artery to the dorsalis pedis artery.

Although exposure of the proximal posterior tibial and peroneal vessels can be gained by extending the tibioperoneal trunk dissection distally, more distal exposure of these vessels is best gained through targeted medial incisions. The posterior tibial artery is found beneath the divided musculotendinous origin of the soleus muscle, and the peroneal artery is deeper and more lateral. The posterior tibial artery at the level of the ankle is a relatively easier target given the proximity of the vessel to the skin surface. The initial incision is made just posterior to the medial malleolus, and the artery exposed by division of the overlying retinaculum. Further distal dissection allows access to the bifurcation and medial and lateral plantar branches.⁷⁰ The more distal peroneal artery may be approached laterally via an incision placed over the distal fibula. Excision of a short segment of fibula will expose the underlying artery.

Figure 93-8. Exposure of the popliteal artery below the knee. The medial incision is made directly overlying the course of the greater saphenous vein (A), with posterior retraction of the gastrocnemius muscle (B), to reveal the popliteal vessels in the popliteal fossa (C).

The anterior tibial artery is typically approached from the anterolateral aspect of the calf (Fig. 93-9) and is found deep within the anterior compartment with the adjacent deep peroneal nerve and anterior tibial veins. It is best identified by developing the intermuscular plane between the tibialis anterior muscle belly medially and the extensor digitorum longus laterally. The dorsalis pedis artery is easily exposed through an axial incision on the dorsum of the foot just lateral to the extensor hallucis longus tendon (Fig. 93-9). The artery lies just deep to the extensor retinaculum.

Figure 93-9. Placement of incisions for femoropopliteal and femorotibial bypass and for greater saphenous vein harvest. These should avoid the incision lines for a below-knee amputation.

Autogenous Vein Bypass

10 Infrainguinal bypass surgery is best performed with autogenous vein conduit, preferably the ipsilateral greater saphenous vein if available.⁹⁶ This preference is particularly true for grafts extending below the knee, where prosthetic conduits of Dacron or polytetrafluoroethylene have significantly poorer patency rates. The first report of a femoropopliteal bypass graft using autogenous greater saphenous vein in a reversed orientation was by Kunlin in 1951.⁸ Given the orientation of the vein valves, the vein can be reversed such that the distal end of the vein is sewn to the proximal inflow

artery and the larger proximal end of the vein is sewn to the distal outflow artery. However, it is our general practice to utilize the greater saphenous vein in the nonreversed orientation as will be discussed shortly. The vein is harvested through a long incision overlying the course of the vein or by more tedious but less invasive sequential skip incisions with intervening cutaneous skin bridges (Fig. 93-7). All side branches are ligated and after harvest, the vein is cannulated and gently dilated with a solution containing heparin and papaverine to assess its suitability. Veins with chronic fibrosis or that fail to dilate to a diameter of 3 mm or greater will likely have poor long-term function.

An alternative and less invasive approach to saphenous vein harvest involves the use of endoscopic technology. In the case of harvesting of the greater saphenous vein, small skin incisions are made over the saphenofemoral junction and the distal vein, and guided by a videoscope inserted distally and advanced proximally, the side branches of the vein are serially identified and either cauterized or clip-ligated. The vein is then divided distally and proximally and removed, leaving the overlying skin undisturbed. Advocates of this method cite a significant reduction in wound complication rates and reduced rates of hospital stay.⁹⁷ Although it has not been widely adopted by vascular surgeons, the technique does have particular theoretical appeal in cases, for example, when contralateral saphenous vein is to be utilized or the healing potential of the donor leg is compromised.⁹⁸

For prosthetic grafts, a tunnel is usually fashioned through the subsartorial plane between the groin incision and the above-knee popliteal space in the interests of protecting the graft from subsequent infection. For vein conduits, it remains the surgeon's preference as to whether the graft is tunneled deeply or in a superficial location in the subcutaneous space. The more superficial configuration greatly facilitates ongoing clinical examination and ultrasonographic surveillance as well as later surgical revision, but carries a risk of graft exposure should there be wound healing problems. Occlusion from trauma to grafts placed superficially has been of theoretic, but not practical concern.

It is our practice to perform the proximal anastomosis prior to the distal anastomosis. First, this allows confirmation of adequate inflow before the bypass is performed. Second, performance of the proximal anastomosis first allows the graft to be tunneled and tailored to appropriate length under arterial pressure. This is of critical importance to prevent kinking along the length of the graft. Some surgeons also prefer to mark the distended graft to ensure against mechanical twisting of the graft during the tunneling process. An additional benefit of performing the proximal anastomosis first is that adequacy of flow through the graft can be assessed, both before and after tunneling, with brief release of the clamp.

Prior to occluding the inflow vessel, the patient is systemically anticoagulated with 5,000 to 10,000 units of heparin. Additional heparin is given throughout the procedure to maintain the activated clotting time near the target range of 250 to 300 seconds. After allowing sufficient time for the heparin to circulate, atraumatic vascular clamps are placed proximally and distally and the artery is incised. The vein is then spatulated and a beveled anastomosis carried out. Typically a 5-0 monofilament suture of polypropylene is used for the femoral anastomosis, a 6-0 is used at the popliteal level, and a very fine 7-0 suture used at the tibial or pedal level. If the target tibial vessel is deep within the calf and visibility is challenging, a technique of "parachuting" the heel of the distal anastomosis is often employed. After completing the proximal anastomosis, the graft is carefully tunneled under arterial pressure. Occasionally, such extensive calcification of the target vessel is encountered that the risk of a significant injury from clamping, even with the minimally traumatic clamps in use today, is prohibitively high. In such cases, proximal inflow and distal artery back-bleeding can be controlled by occlusion balloons placed intraluminally. For distal anastomoses at the knee or more distal level, another alternative technique is the use of a proximally placed sterile pneumatic tourniquet. This technique is particularly advantageous when sewing to diminutive distal tibial or pedal targets, where the impact of a crush injury or plaque dislodgment on graft function could be considerable. Removing the need for clamps by using the tourniquet has two further advantages. First, it improves the operative visibility. Second, and more importantly, given that less longitudinal and circumferential dissection is needed, the degree of vessel spasm and venous bleeding that frequently accompanies vessel exposure at this level is kept to a minimum.

Flow through the graft and the outflow arteries are assessed following completion of the bypass with a continuous-wave Doppler. Ideally, a contrast angiogram is also performed after directly cannulating the proximal graft (Fig. 93-10); this allows for immediate repair of any technical defects that are identified, such as intraluminal thrombus, twisting or kinking of the graft, or retained valve cusps.⁷³ Intraoperative completion duplex ultrasonography is an additional sensitive screen for hemodynamically significant abnormalities within the graft, and its use further serves to prevent early graft loss caused by

correctable technical problems.^{99,100}

^a4-year data.
PTFE, polytetrafluoroethylene.

Current reports of the 5-year results of reversed saphenous vein graft using modern techniques have

been excellent, with primary and secondary patency rates of up to 75% and 80%, respectively and limb salvage rates greater than 90% (Table 93-2).^{69,101-103}

In Situ Grafting

There has been ongoing enthusiasm in some circles for in situ vein bypass grafting, whereby except for its proximal and distal extent, the greater saphenous vein is left undisturbed in its native bed. This technique was first described in 1962, but was later popularized by Leather and Karmody in the late 1970s.^{104,105} Recent reports of in situ saphenous vein grafting have indicated 5-year graft patency rates of up to 80% and limb salvage rates of 84% to 95% (Table 93-1).^{57,102,106-108}

The in situ approach minimizes trauma to the vein during excision and handling and in theory enhances preservation of the vasovasorum and endothelium. It further lowers the considerable risk of wound healing complications seen with traditional vein harvesting, increases vein utilization, and facilitates the creation of more technically precise anastomoses because the proximal and distal vein diameters are more closely matched to those of the inflow and outflow target vessels (Fig. 93-11). The extent of the proximal vein mobilization is dictated by the location of the saphenofemoral junction relative to the proposed site of the proximal anastomosis. It may at times be necessary to perform an endarterectomy of the superficial femoral artery if the length of proximal vein is insufficient. Lysis of the valve cusps is obligatory given the nonreversed configuration, and is facilitated by newer, less traumatic valvulotomes that function safely through the blinded segments of undissected graft. Critics of this technique argue that the advantages listed above have not translated into improved graft function or patency. They further argue that the time required and dissection involved in finding and ligating substantial side branches that can develop into physiologically important AVFs that “steal” distal flow obviates the stated benefits of this approach.

Angioscopic-assisted valve lysis has been employed for over a decade, but has not gained widespread favor. Although there is a significant learning curve with this technology and operative times, at least initially, are significantly prolonged, advocates cite fewer wound complications, shorter hospital stays, and decreased recuperative periods as potential benefits. Proponents of routine angioscopy for direct visualization of valve lysis stress its particular utility in demonstrating such unsuspected endoluminal venous pathology as phlebitic strictures, webs, and fibrotic valve cusps.¹⁰⁹ This adjunct may be particularly useful in cases in which arm vein is used because endoluminal pathology is more frequently encountered and is presumably responsible, in part, for suboptimal results.¹¹⁰

Nonreversed Saphenous Vein Grafts

Recognizing the many practical advantages inherent to the in situ technique, some surgeons have modified the approach to infrainguinal bypass grafting with venous conduit to incorporate several of the same principles.⁵⁶ In particular, if the harvested vein is tapered to any significant extent, it is used in a nonreversed fashion. By optimizing the size matching between the artery and vein at both the proximal and distal anastomosis sites as discussed previously, one can often accept for use, smaller veins than would be unsuitable for reversed vein grafting. The nonreversed configuration also allows preservation of the saphenous vein hood, which both extends the available conduit length and is especially beneficial when the femoral artery is thick walled and diseased.

The vein is harvested and dilated in a similar fashion to reversed vein grafts and the cusps of the proximal valve of the greater saphenous vein are excised under direct vision with fine Potts scissors. There are currently two main types of valvulotomes available. The modified Mills valvulotome is a short, metal, hockey stick-shaped cutter that can be introduced through the distal end of the vein or through the side branches. After the proximal anastomosis is performed, and with the perfused conduit on gentle stretch, the valves are carefully lysed in a sequential fashion by pulling the valvulotome inferiorly. An alternative, recently designed self-centering valvulotome allows lysis of all valves in a single pass and is thought by some to be less traumatic. Once acceptable pulsatile flow is ensured, the distal anastomosis is performed in the standard fashion.

It is important to note that similar patency rates have consistently been demonstrated regardless of which technique is applied, and so surgeon preference and comfort level is an acceptable reason for choosing one method over another.^{107,108}

Prosthetic Bypass

It is recommended that infrainguinal bypass surgery be performed with saphenous vein or an autologous substitute whenever feasible given the clearly demonstrated enhanced patency rates.^{51,111}

Some institutions more frequently rely on prosthetic grafts. When the distal target is the above-knee popliteal artery and the tibial outflow is relatively well preserved, this is an acceptable approach, as patency rates in this situation approach those of vein grafts.¹¹² A variety of surgical adjunctive procedures, from patching the distal anastomotic target vessel to the creation of a distal AVF or various autogenous vein cuffs interposed between the distal prosthetic and the target artery, have all been attempted as a means of improving the patency rates of grafts extending below the knee.¹¹³ Polyester (Dacron) and polytetrafluoroethylene (Teflon) grafts are the two main types of prosthetic available and, as in other anatomic positions, available data show generally equal results with either choice. The entire procedure is carried out through two small proximal and distal incisions between which the graft is tunneled anatomically. The selection of a 6-, 7-, or 8-mm graft is dictated by the size of the native vessels.

Figure 93-11. A: In the in situ method of infrainguinal reconstruction, the saphenous vein is left undisturbed in its native bed except for at the proximal and distal anastomotic sites, in this case, the common femoral artery and the tibioperoneal trunk, respectively. B: The saphenofemoral junction is transected in the groin, the venotomy in the femoral vein is oversewn and the proximal end of the saphenous vein spatulated is prepared for anastomosis. C: After the first venous valve is excised under direct vision, the graft is anastomosed end-to-side to the femoral artery. Flow is then restored through the vein graft and the valvulotomy

passed from the distal end to lyse the residual valves (**D**), before the distal anastomosis is performed (**E**).

Reoperative Bypass Surgery

As the patient population treated by vascular surgeons has increased in age, and more and more challenging cases are accepted for primary treatment, there has been a corresponding increase in the incidence of reoperative bypass surgery performed for infrainguinal arterial occlusive disease. Such reoperative procedures are particularly challenging, both because of the scarring present at the inflow and outflow target sites and because there is typically a lack of ipsilateral greater saphenous vein. Whenever possible, the first problem is addressed by choosing anastomotic sites just above or below the previous touchdown points, thereby avoiding dissection through often densely scarred tissue planes. When ipsilateral greater saphenous vein is absent because of prior infrainguinal or coronary artery bypass surgery or prior saphenous vein stripping, there are a number of alternative conduit sites available. Investigators examining the consequence of using the contralateral greater saphenous vein in these situations found it to be the optimal conduit; despite the presumably high incidence of contralateral lower extremity as well as coronary occlusive disease in this population, the short- and long-term impact was found to be minimal.⁹⁰

In the absence of any greater saphenous vein, preoperative venous duplex ultrasonography is employed to evaluate the cephalic and basilic veins of the arms and the lesser saphenous veins of the legs in an effort to determine the best conduit available. Often the veins distal to the antecubital crease are scarred and of small caliber, but their more proximal counterparts are often of excellent size and quality. The use of arm veins in general can be technically challenging and for that reason has not been universally adopted. The dissection of the basilic vein can be particularly tedious as it has multiple side branches and lies adjacent to several important nerves. As arm veins are often relatively short, a venovenostomy is often required to create composite grafts long enough to complete the arterial reconstruction (**Fig. 93.12**). This is performed with generous spatulation of each vein hood to create a widely patent vein-to-vein anastomosis. Given their thin-walled nature, arm vein grafts are also quite prone to twisting and kinking, and special care must be taken during the tunneling process to avoid these problems. The more proximal arm veins can be relatively large, and it is often advantageous to use one or more of the segments in a nonreversed fashion to better match the graft to the inflow vessel size.

Figure 93-12. Creation of a composite graft from two or more segments of arm vein or lesser saphenous vein (A) is sometimes necessary to obtain the desired length of fully autogenous conduit for infrainguinal bypass. A widely spatulated venovenostomy (B and C) is optimal.

Not surprisingly, the results of reoperative infrainguinal bypass surgery do not match those of primary reconstruction. With autogenous vein, 5-year patency rates of 60% and limb salvage rates of 70% to 80% have been reported.^{27,114} Coumadin is often used postoperatively in patients with compromised outflow or in whom the conduit was of marginal quality and has been associated with improved long-term patency.¹¹⁵

Postreconstruction Management

11 Many patients undergoing surgical reconstruction for critical ischemia with tissue loss require one or more adjunctive operative procedures of their foot. Small, uninfected ulcerations of the toe or foot often can be safely managed conservatively. However, larger, gangrenous lesions of the toe, forefoot, or heel usually require débridement of all necrotic tissue at the completion of the revascularization procedure. If the ischemia is particularly severe or infection is present, a toe or transmetatarsal amputation may be necessary in order to achieve a margin of healthy tissue. This is particularly important in patients with diabetes or end-stage renal disease, in whom persistent infection or necrosis can result in limb loss despite the presence of a well-revascularized extremity. The wounds are usually left open and treated with moist occlusive dressings or negative-pressure wound therapy. Serial débridements on the ward or in the operating room are often necessary for the larger wounds, which can then be surgically closed after an interval healing period or allowed to slowly close via secondary intention over time.

Unless otherwise contraindicated, all patients are maintained indefinitely on an antiplatelet regimen with either aspirin or clopidogrel following surgical bypass. As stated previously, in cases in which a graft is at increased risk of failure, such as in the setting of reoperation or in cases in which compromised outflow or a marginal conduit was accepted, the antiplatelet agent may be supplemented with heparin and then warfarin.¹¹⁵ Patients with distal calf or pedal incisions should have consistent leg elevation in the early postoperative period to minimize leg swelling and wound healing complications. Thereafter, aggressive rehabilitation maximizes the chances of, and shortens the time to a return to full function after extensive reconstructive surgery. Ongoing risk factor modification in the form of smoking cessation, lipid reduction, exercise, blood pressure management, and diabetic blood sugar control is of further paramount importance in minimizing the risk of disease progression or recurrence.¹¹⁶

Graft Failure and Surveillance

Postoperative graft failures are typically classified according to the time interval from surgery as early, intermediate, or late. Graft thrombosis occurring within 30 days, the so-called “early graft failures,” are generally thought to be a result of technical or judgment errors by the surgeon. Included in this list would be such technical errors as twists, kinks, incompletely lysed valves, or anastomotic defects, as well as judgment errors in using a poor quality vein or targeting an outflow vessel with inadequate runoff to support the graft. Intermediate graft failures include those between 30 days and 2 years and are generally attributed to the proliferation of intimal hyperplasia at the anastomoses or prior valve sites within the graft (Fig. 93-13). Late graft failures occurring beyond 2 years are typically a result of the progression of atherosclerotic occlusive disease within the inflow or outflow arteries.

Figure 93-13. Arteriogram demonstrating severe stenosis of distal graft from intimal hyperplasia, likely at prior valve site.

Given the known incidence of graft failure and the potentially dire consequence in terms of limb salvage or preservation of limb function in a patient with limited options for secondary or tertiary bypass, the ability to maintain graft patency through early identification and prompt correction of graft stenosis is of paramount importance.¹¹⁷ Serial postoperative surveillance scanning with duplex ultrasound has proven an excellent means of accurately identifying hemodynamically significant stenosis within the vein graft that threaten the graft patency.¹¹⁸ Velocity criteria have been developed for high-grade lesions that may warrant either more intensive surveillance or prophylactic intervention. Absolute velocities less than 40 cm/s or greater than 300 cm/s or a three-fold increase in velocity in one segment compared with that of an adjacent segment are all indicative of impending graft failure. Confirmation by angiography and expeditious treatment by percutaneous cutting balloon angioplasty, surgical patch angioplasty, or interposition grafting of such significant lesions minimizes the risk of graft thrombosis and ensures optimal long-term graft patency.

Complications

The most commonly seen major complications of infrainguinal bypass surgery are cardiac in nature, and include myocardial infarction, congestive heart failure, and arrhythmias. In a recent review spanning 20 years and involving more than 1,600 procedures, the perioperative myocardial infarction rate was 3%, and the rate of cerebrovascular accident was 1%.¹⁰¹ Patients with diabetes mellitus or preoperative renal insufficiency are at particular risk for developing postoperative renal failure (defined as an elevation of serum creatinine >3 mg/dL, doubling of the serum creatinine or the need for hemodialysis), which is seen in up to 2% of patients overall. Patients undergoing lower extremity revascularization are also prone to wound complications, given the length of incisions and the prolonged operating times often required. Overall wound complications, including cellulitis and abscess formation, wound dehiscence, and skin flap necrosis, can occur in up to 40% of patients and can best be avoided by gentle handling of the tissue and the use of skin bridges and careful avoidance of skin flaps during vein harvesting.¹¹⁹ Postoperative hematomas, usually caused by slow capillary or venous oozing, or seromas are seen in 5% of patients; and less commonly encountered hemorrhage, typically a result of either a slipped vein branch ligature or anastomotic disruption, is seen in less than 1% of cases.

ACKNOWLEDGMENT

This chapter is based on the previous version from the 5th edition entitled *Femoropopliteal and Tibial Occlusive Disease* by William P. Robinson, Matthew T. Menard, and Michael Belkin.

Chapter 94

Lower Extremity Amputation

Matthew J. Sideman, Kevin E. Taubman, and Bradley D. Beasley

Key Points

- 1 The annual incidence of amputations is decreasing.
 - 2 The vast majority of lower extremity amputations are performed for complications of diabetes or arterial insufficiency.
 - 3 Emergent amputation is indicated in the face of uncontrolled or ascending infection.
 - 4 Primary amputation is occasionally indicated in cases of treatment for lower extremity trauma.
 - 5 Revascularization is often performed in conjunction with a minor amputation, either simultaneously or as a staged procedure.
 - 6 The choice of amputation level depends on the indication for the procedure, the condition of the patient, and the rehabilitation potential of the patient.
 - 7 The energy required to ambulate following a lower extremity amputation increases with ascending level of amputation.
-

1 Surgeons are often involved in treating patients requiring lower extremity amputation. Increasing incidence of diabetes, peripheral arterial disease, and the aging population has put more patients at risk for amputation. The explosion of endovascular interventions over the past decade has resulted in decreasing numbers of amputations performed annually.¹ A review of the Nation Hospital Discharge Survey and Medicare claims data confirms this negative trend.² Clinical judgment is critical to a successful outcome. Factors to consider are primary amputation, revascularization, repeat revascularization, level of amputation, and timing of amputation. The surgeon must remember that the goal is to maintain maximal function of the patient not necessarily maximal length of the limb. Consequently, experience of the surgeon has been shown to be key to a successful outcome.³

INDICATIONS

2 Most lower extremity amputations are performed for complications of diabetes or arterial insufficiency ([Table 94-1](#)). Chronic infection and trauma account for less than 10% of the total number of amputations. Other indications include neuroma, frostbite, malignancy, chronic pain, arterial embolization, venous insufficiency, and cryoglobulinemia.⁴

Elective lower extremity amputation in diabetic and vascular patients is indicated for gangrene (dry gangrene), gangrene with infection (wet gangrene), unremitting and unreconstructable rest pain, and nonhealing ulcers. The goal of the operation is to remove all nonviable tissue, relieve ischemic rest pain, ensure primary wound healing, and facilitate rehabilitation. Elective amputation should only be performed following an evaluation for revascularization procedure by a surgeon capable of performing such procedures. Veith et al.⁵ reported that 96% of patients who underwent lower extremity arteriography for limb-threatening infrainguinal arteriosclerosis were candidates for arterial reconstruction. Advances in percutaneous management have expanded treatment options to patients who were not otherwise operative candidates. Not all patients are candidates for arteriography, including those with chronic renal insufficiency, organic brain syndrome, nonfunctional limbs, fixed joint contractures, insensate feet, and those with extensive gangrene.

Spinal cord stimulation (SCS) may offer a chance for limb salvage for patients with chronic ischemia in whom reconstruction is not an option. Based on Melzack and Wall theory for the treatment of chronic pain,⁶ the mechanism of pain relief and increased blood flow in end-stage peripheral vascular disease is unclear. Despite this, there is peripheral vasodilatation on the microvascular level which leads to pain relief,⁷ increased claudication distance,⁸ ulcer healing,⁹ and possible limb salvage.^{7,10,11} The 1-year foot

salvage rate is 60% to 70% on average, according to a review of the literature.¹² SCS is only appropriate when surgery for revascularization is no longer possible. Furthermore, SCS only dilates microvasculature and does nothing for the underlying, progressive peripheral vascular disease that is causing the ischemia. SCS, therefore, is only a temporizing measure, but can potentially give an extended functional period with a procedure that is well tolerated and relatively simple to perform.¹² Recently, Gersbach et al. have shown that the benefits of SCS persist longer than initially thought.¹³

3 Emergent amputation is indicated in the face of uncontrolled or ascending infection. In the case of uncontrolled sepsis, it can even be a life-saving maneuver. A diabetic patient with a foot abscess is a surgical emergency. Frequently, incision and drainage with or without a toe or a combined toe and metatarsal resection is sufficient to control the acute problem. The wounds should be left open in the setting of acute infection. If the process extends beyond the foot, a staged amputation should be performed proximal enough to control the infection. This can include an ankle disarticulation, a guillotine below-knee amputation (BKA), a knee disarticulation, or a guillotine above-knee amputation (AKA). Disarticulations have the advantage of preserving limb length and avoiding an open bone in the incision. After the infection is controlled, the appropriate amputation can be completed. A one-stage primary AKA can be considered in patients who are nonambulatory, have infection involving the entire lower leg, have a fixed knee contracture, or those with a nonfunctional limb. Patients who are too unstable for surgery can be temporized with a cryoamputation.¹⁴

INDICATIONS/CONTRAINDICATIONS

Table 94-1 Indications for Lower Extremity Amputation

Indication	Percentage
Complications of diabetes mellitus	60–80
Nondiabetic infection with ischemia	15–25
Ischemia without infection	5–10
Chronic osteomyelitis	3–5
Trauma	2–5
Miscellaneous (neuroma, frostbite, tumor, pain, and nonhealing wound)	5–10

From Malone JM. Lower extremity amputation. In: Moore WS, ed. *Vascular Surgery: A Comprehensive Review*. Philadelphia, PA: WB Saunders; 1993:810.

4 Primary amputation is occasionally indicated as treatment for severe lower extremity trauma. Both penetrating and blunt injuries of the lower extremities are frequently associated with vascular, nerve, bone, and extensive soft tissue injuries. Several treatment guidelines have been developed for lower extremity trauma. Lange¹⁵ recommended primary amputation for open tibial fractures with associated vascular injuries if the posterior tibial nerve was disrupted in an adult or if the duration of warm ischemia was greater than 6 hours in a crush injury. In addition, he suggested that primary amputation was relatively indicated in patients with polytrauma, severe ipsilateral foot injuries, and in those with an expected protracted postoperative course. These suggestions are supported in work by Bosse et al.¹⁶ demonstrating, in the case of high-energy lower extremity trauma, amputation, and reconstruction have equal functional outcomes at 2 years. Additional guidelines have been provided by Johansen et al.¹⁷ who devised a Mangled Extremity Severity Score to predict the need for amputation based on the extent of skeletal or soft tissue damage, limb ischemia, shock, and age. Unfortunately, none of these guidelines are predictive of functional recovery in patients who undergo limb salvage.¹⁸ Therefore, treatment with primary amputation is an extremely difficult decision and requires extensive clinical judgment as well as multidisciplinary input. Contributing factors include the severity of the injury, the overall clinical status, and the ultimate rehabilitation potential of the patient.

EVALUATION FOR REVASCULARIZATION

Modern vascular surgery techniques allow successful limb salvage in situations not previously possible. All patients who present for possible lower extremity amputation, including minor amputations, should have their peripheral vascular circulation evaluated preoperatively. Any patient with absent pedal pulses or abnormal ankle–brachial indices should be evaluated by a vascular surgeon skilled in both open and endovascular revascularization techniques. The evaluation may require only a thorough

history and physical examination if there is an obvious contraindication to revascularization (e.g., nonfunctional limb, severe organic brain syndrome). Noninvasive vascular laboratory examinations are a mandatory minimum for patients with abnormal vascular examinations. Additional imaging with either multiple-slice computed tomographic angiography (CTA), magnetic resonance angiography (MRA), or contrast angiography can be done based upon the patient's initial evaluation and vascular lab results. The information obtained from these tests is heavily dependent on the quality of the machinery, the skill of the technologist, and the knowledge of the interpreting physician. All of these factors must be taken into account when deciding which test to order. Contrast angiography with selective lower extremity injections may be necessary to fully define the patient's anatomy and suitability for reconstruction; however, it is generally preferred to perform this invasive procedure for preoperative planning or for planned percutaneous intervention. Contrast arteriography should not be considered a *diagnostic* examination.

Exponential advances in endovascular techniques have occurred over the past 10 years. These have found their way into the peripheral circulation and have applicability in limb salvage. Percutaneous techniques include convention balloon angioplasty, stenting (including balloon expandable, self-expanding nitinol, and covered stents), cryoplasty, and percutaneous atherectomy (including laser, directional, and rotational). The BASIL trial showed no significant difference in amputation-free survival among patients with critical limb ischemia when randomized to open or percutaneous revascularization.¹⁹

In terms of surgical reconstruction, upper extremity²⁰ and cryopreserved cadaver vein²¹ have increased the options for conduit in limb salvage situations. Prosthetic grafts with vein cuffs^{22,23} provide other alternatives when appropriate autogenous conduit is not available. More recently, a heparin-bonded prosthetic graft has been introduced and early studies show promising results.²⁴ An operation for limb salvage should never be denied *only* for lack of conduit.

5 Revascularization is often performed in conjunction with a minor amputation, either simultaneously or as a staged procedure. This allows management of the acute problem of sepsis and the underlying chronic ischemia. Caution must be taken if there is active infection and the only available conduit is prosthetic for fear of infecting the graft. Amputation with control of infection followed by revascularization is the more prudent course. In extreme cases, a limited amputation can be combined with revascularization and a tissue transfer (free or rotational flap) to achieve limb salvage.^{25,26}

CHOICE OF AMPUTATION LEVEL

General

6 The choice of amputation level depends on the indication for the procedure, the condition of the patient, and the rehabilitation potential of the patient. The most common amputation levels are illustrated in [Figure 94-1](#). Because most amputations are performed for complications of diabetes or arterial insufficiency, the selected level must remove all nonviable, painful tissue, allow primary healing, and maximize rehabilitation potential. Selection of the amputation level for malignant disease is dependent on the biologic characteristics of the neoplasm and will not be discussed further.

The general medical condition and the rehabilitation potential of the patient are important factors in deciding to proceed with amputation and in selecting the appropriate level. If a patient is ambulatory and independent preoperatively, the level with the greatest likelihood of maintaining function should be selected. If the patient is not ambulatory or has significant comorbid conditions, the primary wound-healing rate should be the determining factor.

Specific Situations

Aggressive attempts to salvage a distal amputation level are not indicated for patients who are unlikely to ambulate with a prosthesis.²⁷ For example, patients with fixed joint contractures greater than 15 degrees at the knee or 10 degrees at the hip are unlikely to ambulate with a prosthesis. BKAs are relatively contraindicated in patients with paraplegia because flexion contractures at the knee can lead to stump ulceration.

Figure 94-1. Common amputation levels for the lower extremity.

Energy Requirement

7 The energy required to ambulate following a lower extremity amputation increases with ascending level of amputation. The more proximal the amputation, the less likely a patient will be able to ambulate postoperatively. [Table 94-2](#) illustrates the increased energy cost of the common lower extremity amputations. In clinical practice, the most significant increase is between a BKA and an AKA. Ambulation on an above-knee prosthesis requires the use of muscle groups poorly suited for that purpose. These increased energy costs are minor issues for young trauma or cancer patients; however, they represent a considerable obstacle for the older diabetic or vascular patient.

Clinical Assessment

The primary preoperative consideration for wound healing is the status of the skin and muscle blood flow. Operative technique, the patient's nutritional status, and the presence of infection also affect wound healing. Clinical judgment by an experienced surgeon accurately predicts healing of a BKA in approximately 80% of cases.²⁸ A palpable pulse at the level immediately proximal to the proposed amputation essentially ensures healing;²⁹ however, the converse is not true. Noninvasive arterial testing is the most common adjunctive test used to predict healing of a specific amputation level. Its usefulness is limited when medial sclerosis prevents vessel compression, a condition common in diabetic patients. Because the digital vessels are often spared from this process, digital pressure readings may be helpful in this setting. Transcutaneous oxygen measurement has been shown to predict primary healing although it is less able to predict failure to heal.^{30,31} It has become more widely available and has supplanted previous less reliable tests that were more limited in availability. [Tables 94-3](#) to [94-6](#)

summarize the results of various preoperative tests to predict wound healing for toe, foot and forefoot, below-knee, and AKAs, respectively.

Table 94-2 Rehabilitation Energy Cost of Amputation at Various Levels

Amputation Level	Energy Cost
Digital or ray	Minimal (except first ray)
Transmetatarsal	Minimal during normal walking
Below-knee	30–60% increase in energy required for ambulation
Above-knee	60–100% increase in energy required for ambulation
Hip disarticulation	100–110% increase in energy required for ambulation

OPERATIVE TECHNIQUE

General Considerations

Diabetic patients who present septic require adequate fluid resuscitation, broad-spectrum antibiotics (including anaerobic coverage), and an emergent operation. Whereas maintenance of limb length and function is admirable, control of sepsis and wide débridement of all nonviable tissue are essential and potentially lifesaving. All patients require atraumatic tissue handling. Avoid forceps on the skin edge. Excessive skin flaps and dead space are also not desired. Amputations done in the face of active infection are kept open and treated with dressing changes. Consider delayed primary closure in cases where perfusion is intact.

RESULTS

Postoperatively, the limb is elevated to minimize tissue edema and promote healing. Weight bearing on the amputation is delayed until healing is assured. This patient population requires effective prophylaxis against deep venous thrombosis and venous thromboembolism.

Digital and Ray Amputations

Digital amputations are indicated for some severe and irreducible deformities as well as gangrene or osteomyelitis localized distal to the base of the proximal phalanx. A technique for partial digital amputation is illustrated in [Figure 94-2A](#). The circumferential or racquet-shaped skin incision is made over the distal end of the proximal phalanx, and carried down to bone. Nerves and tendons are transected under tension and allowed to retract. The proximal phalanx is divided with bone shears or power saw and the transected end smoothed with a rongeur. Soft tissue coverage can be performed with either medial/lateral flaps or dorsal/plantar flaps depending on skin tension and viability. The wound is closed only with simple interrupted skin sutures. Judicious use of subcutaneous sutures is advised due to danger of vascular compromise to the small remaining flaps. Non-weight bearing restrictions or protected weight bearing on the heel only in a rigid soled postoperative shoe or walking boot until the wound heals is recommended.

A ray amputation is indicated when the disease process extends to the metatarsal phalangeal joint. The technique is similar to a digital amputation and is illustrated in [Figure 94-2B](#). A circumferential incision is made at the base of the involved toe and extended proximally on the dorsum of the foot over the metatarsal. The incision is extended to bone. The periosteum is cleared circumferentially and the bone is transected using a power saw at a level that will allow tension-free closure of the wound. In the case of the first or fifth toe, the incision is extended on the medial or lateral aspect of the foot, respectively. Care should be taken to bevel the distal metatarsal stump to minimize any prominence that may lead to skin breakdown with weight bearing or shoe gear wear. Typically the first metatarsal is beveled from proximal medial to distal lateral and proximal planter to distal dorsal. Metatarsals 2, 3, and 4 should be beveled from proximal plantar to distal dorsal. The 5th metatarsal is beveled from proximal lateral to distal medial and proximal plantar to distal dorsal.

In selected cases of neuropathic ulcers, the metatarsal head can be resected leaving the toe intact. A dorsal longitudinal incision is made over the metatarsal bone and the metatarsal head is resected with a power saw. Pulsed lavage and careful soft tissue inspection will help guide appropriate care for the

plantar wound (i.e., packing, negative pressure therapy or ellipse of wound with closure). The dorsal wound is typically closed unless severe infection is encountered.

Transmetatarsal Amputation

Transmetatarsal amputation (TMA) is a useful procedure that maintains a patient's ability to ambulate without the aid of a prosthesis. It is indicated when the gangrenous or infectious process involves multiple digits or a portion of the forefoot. Care must be taken to plan for the appropriate soft tissue coverage if primary closure is desired. Maximizing the plantar flap is most common, but coverage can also be gained from medial or laterally based flaps and even filleted toe flaps. If adequate soft tissue coverage is not available and a more proximal foot amputation (i.e., Chopart joint amputation) is not desired then an open amputation through the metatarsal bones can be performed. The wound is allowed to close secondarily or covered with a skin graft. Skin grafts in this position, however, are susceptible to breakdown secondary to the pressure related to ambulation.

From Durham JR. Lower extremity amputation levels: indications, methods of determining appropriate level, technique, prognosis. In: Rutherford RB, ed. *Vascular Surgery*, 3rd ed. Philadelphia, PA: WB Saunders; 1989:1707.

The technique is demonstrated in [Figure 94-3](#). A skin incision is made on the dorsum of the foot immediately proximal to the metatarsal heads and extended medially and laterally to a point midway

between the plantar and dorsal surfaces. The plantar incision is made along the digital crease and extended diagonally medially and laterally to connect to the dorsal incision. The dorsal incision is deepened to the periosteum, which is cleared with a small periosteal elevator. The metatarsal bones are transected 0.5 to 1.0 cm proximal to the dorsal skin incision. The plantar flap is fashioned by continuing the dissection just superficial to the metatarsal heads. Care is taken to maintain plantar flap thickness. The nerves and tendons are transected sharply under tension and allowed to retract. The plantar flap is rotated anteriorly and assessed for length. Excess tissue is excised sharply and the deep tissue is approximated with absorbable suture. The skin is closed without tension using monofilament suture or skin staples.

Weight bearing is delayed for 1 month to allow adherence of the plantar flap. Either a soft dressing or a short leg cast can be used for a postoperative dressing.

Staging a tendo-achilles lengthening (TAL) is important to consider following (or at the same time if no infection is present) a partial foot amputation. Ulcer formation at the TMA stump site is often related to equinus formation due to the ensuing flexion/extension imbalance that occurs after resection of the forefoot. A simple triple-hemisection percutaneous TAL can effectively lengthen the achilles and reduce future pressures at the stump site.³² Other tendon-balancing procedures may be needed to control varus and valgus contraction deformities that can develop.

Figure 94-2. **A:** Digital amputation. A circumferential skin incision is made proximal to the gangrenous process. The proximal phalanx is transected and the soft tissue approximated. **B:** Metatarsal head resection (ray amputation). A racquet-shaped skin incision is made with the circular component extending circumferentially around the digit and the longitudinal component extending proximal to the metatarsal head. The metatarsal is transected proximal to the head and the soft tissue approximated.

Syme Amputation

The Syme amputation is a foot amputation that preserves limb length and the epiphyseal growth plates, and allows occasional ambulation without a prosthesis. It is indicated in cases of extensive foot trauma or other nonviable tissue conditions distal to the hindfoot. The Syme amputation is contraindicated if a

supple intact heel pad and a well-vascularized hindfoot tissue flap are not available.

The procedure can be performed in one or two stages, as illustrated in [Figure 94-4](#). The initial steps for both procedures are identical, except that the skin incision for the two-stage procedure is located 1.5 cm more distally. The skin incision for the one-stage procedure extends from the medial to the lateral malleolus in the horizontal and vertical planes. The dorsal incision is extended to the bone, and the tendons are transected under tension. The anterior tibial artery is identified, divided, and suture ligated. The dissection is carried into the tibiotalar joint space as the foot is forcibly plantar flexed. The ligaments are transected and the talus is dislocated. The plantar aspect of the incision is deepened to the calcaneus, and the calcaneus is sharply dissected from the plantar fascia. The plantar fascia is densely adherent and care must be taken to prevent damage to the heel pad, especially at the level of the Achilles tendon. The posterior tibial artery must be preserved, because it perfuses the heel pad. The foot is then removed. The two procedures differ from this point forward.

In the one-stage procedure, the medial and lateral malleoli are transected flush with the tibiotalar joint space, and the heel pad is rotated over the ends of the tibia and fibula. The deep fascial layers are approximated with absorbable suture and the skin is closed with monofilament suture or skin staples. Securing the distal end of the remaining plantar fascia to a small drill-hole in the distal anterior tibia will help anchor the plantar flap and reduce posterior migration. In the two-stage procedure, the heel pad is similarly positioned and the wound is closed without further bone transection. In 6 weeks, elliptical incisions are made over the medial and lateral malleoli and the distal ends of the tibia and fibula are transected flush with the ankle joint. In addition, the distal flares of the tibia and fibula are transected, creating the rectangular stump of the two-stage procedure. The wound is closed in a similar fashion. For both procedures, weight bearing is delayed for at least 4 weeks to allow heel pad fixation. A soft dressing or a short leg cast can be used.

Below-Knee Amputation

The complications of diabetes and arterial insufficiency constitute most of the indications for BKAs. [Tables 94-5](#) and [94-6](#) outline the criteria used to decide between a BKA and an AKA in this setting.

Figure 94-3. A: The skin incision for the transmetatarsal amputation is made on the dorsum of the foot immediately proximal to the metatarsal heads and on the plantar surface within the digital crease. B: The metatarsal heads are transected proximal to the

skin incision and separated from the plantar soft tissue flap along a plane adjacent to the bone. C: The plantar soft tissue flap is rotated anteriorly and approximated.

The most common technique, using a long posterior flap, is illustrated in [Figure 94-5](#). When gangrene, wounds, or incisions preclude the use of a posterior flap, equal anteroposterior or sagittal flaps can be used; however, the posterior flap is associated with the highest incidence of primary healing and is thus preferred whenever possible. This higher rate of healing reflects the fact that the posteriorly located gastrocnemius and soleus muscles are supplied by the sural arteries that originate proximal to the knee.

The proposed skin incision is drawn on the leg with a marker. The tibia should be transected 10 cm distal to the tibial tuberosity and the anterior aspect of the skin incision should be 1 cm distal to the site selected for the tibial transection. The anterior incision is extended medially and laterally. The length of the anterior incision should equal two-thirds of the circumference of the leg at the proposed level of the tibial transection. The incision is then extended longitudinally along the medial and lateral aspects of the leg. The length of the longitudinal incisions should equal one-third of circumference of the leg at the level of the tibial transection. It is prudent to err on the side of making the posterior flap too long and trim excess length at the time of closure. The medial and lateral incisions are connected posteriorly. Curving the transitions of the incision prevents the accumulation of redundant tissue at the medial and lateral aspects of the completed amputation. The skin incisions should be down to the fascia to allow separation of the skin edges. This step decreases the chance of inadvertent injury to the posterior flap later in the procedure; however, the greater and lesser saphenous veins need to be ligated and transected.

The anterior aspect of the incision is deepened through the periosteum of the tibia. The muscles of the anterior compartment are divided at the level of the skin incision and the anterior tibial neurovascular bundle is identified and suture ligated. The proximal tibia is circumferentially cleared of periosteum, and transected 1 cm proximal to the skin incision. The anterior aspect of the tibia is cut on a 45-degree angle. The fibula is cleared and transected 1 cm proximal to the transected tibia. The bones are divided with either a power-driven reciprocating saw, or a manual saw. Regardless, care must be taken to avoid trauma to the anterior skin flap.

The posterior tibial and peroneal neurovascular bundles are identified and suture ligated. The tibia is retracted anteriorly and the posterior musculature is divided along the plane of the longitudinal skin incisions using an amputation knife. Extreme caution must be taken to avoid injury to the skin edges of the posterior flap during this step. Often a scalpel is needed to complete the division of the gastrocnemius tendon distally. The specimen is removed and manual compression achieves temporary hemostasis while the remaining vascular structures are identified and ligated. The posterior tibial nerve is retracted distally, ligated, transected sharply, and allowed to retract. The posterior flap is rotated anteriorly to assess thickness and length. Frequently, the musculature needs to be debulked to allow a tension-free closure. Rough edges of the bones are filed smooth and the wound is irrigated. Bone wax is not used. A closed-system drain may be placed to prevent a hematoma. The end of the tibia is covered and stabilized with the deep posterior musculature using absorbable sutures. The gastrocnemius fascia is approximated to the anterior fascia using absorbable suture. The subcutaneous tissue is closed with absorbable suture to minimize tension on the skin edges and the skin is closed with monofilament suture or staples.

Figure 94-4. **A:** The skin incision for the one-stage Syme amputation connects the medial and lateral malleoli in both the horizontal and vertical planes. The skin incision for the two-stage procedure is located approximately 1.5 cm further distally. **B:** The incision is extended into the tibial—talar joint space, and the foot is placed in forced plantar flexion. **C:** The calcaneus is sharply dissected from the adherent plantar fascia along a plane adjacent to the bone. **D:** The heel pad is rotated anteriorly and approximated after the calcaneal dissection in the two-stage procedure and after the additional transection of the medial and lateral malleoli in the one-stage procedure. **E:** Elliptic incisions are made over the medial and lateral malleoli during a second operation for the staged procedure. The medial and lateral malleoli are transected flush with the ankle joint, and the distal flares of the tibia and fibula are removed. **F:** The two-stage procedure results in a less bulbous, more cosmetically acceptable residual limb.

Figure 94-5. A: The skin incision for a below-knee amputation based on a posterior flap is made 11 cm distal to the tibial tuberosity and extended medially and laterally to the midpoint of the calf. The length of the posterior flap is about 2 cm longer than the diameter of the calf at the point of the proximal incision. B: The tibia is transected 1 cm proximal to the skin incision. The fibula is transected an additional 1 cm proximal to the level of the tibial transection, and the posterior calf muscles are incised along the plane of the skin incision. C: The anterior aspect of the tibia is beveled at an angle of about 45 degrees, and the bone edges are filed. D: The posterior flap is rotated anteriorly and approximated.

The length of the BKA may be shortened if required by the infectious or gangrenous process. Although not ideal, a short BKA is functionally superior to an AKA. In the extreme case, the tibia can be transected at the level of the tibial tuberosity and the stump can still be fit with a prosthesis. If a BKA is necessary at this level, the biceps tendon and collateral ligament should be sutured to the tibia, the common peroneal nerve should be transected above the knee, and the fibula should be removed.

A variation of the BKA is the osteomyoplastic transtibial amputation also known as the Ertl amputation. This technique has been well described³³ and involves creating a bone bridge between the tibia and the fibula using a piece of the amputated fibula. Proposed advantages of this technique include a more stable end-bearing of the stump and prevention of fibular instability.

In the face of extensive foot infection, an open (guillotine) amputation should be performed as the first part of a staged procedure. A circumferential incision is made in the distal leg just proximal to the malleoli. The fascia is divided, and the tibia and fibula are dissected free. The bones are divided at the level of the skin incision. All major neurovascular bundles are suture ligated and the remaining soft tissue is divided to complete the amputation. Several sutures are placed through the skin and underlying fascia to prevent retraction. The wound is left open and dressed. A negative pressure dressing may be used and simplifies wound care. A definitive BKA is delayed until the infectious process has resolved which typically occurs within a week. Ankle disarticulation is an alternative to a guillotine BKA. An incision is made at the level of the ankle joint. Vascular structures are suture ligated. The tendons are divided sharply entering the ankle joint. The capsule is circumferentially incised removing the foot from

the leg. The wound is packed open.

Above-Knee Amputation

An AKA is indicated for patients requiring an amputation with a fixed-knee contracture, a nonfunctional limb, or insufficient circulation to heal a BKA. Typically, a transverse fish-mouth incision is made in the lower thigh. The initial skin incision should be carried through the subcutaneous tissue to allow the edges to separate. This step will decrease the likelihood of inadvertent injury to the posterior skin flap during transection of the posterior muscle groups. The greater saphenous vein needs to be identified and ligated. The dissection is carried down to the femur that is cleared using a periosteal elevator to a level 2 to 3 cm proximal to the skin incision. The superficial femoral artery is dissected free and suture ligated. The bone is transected with a reciprocating or manual saw, and the posterior muscle flap is divided with an amputation knife. Manual compression with a laparotomy pad on the newly divided stump will easily control hemorrhage while vessels are identified and ligated or electrocoagulated. The sciatic nerve is identified and placed on gentle traction. It is then highly ligated, sharply divided, and allowed to retract into the wound. The flaps should be power irrigated and hemostasis assured. The fascia is then closed with absorbable suture. The subcutaneous tissue is closed with absorbable suture to minimize tension on the skin edges and the skin is closed with monofilament suture or staples. Alternative incisions can be made to accommodate surgical wounds. Most AKA wounds will heal even when the femoral pulse is nonpalpable. More proximal thigh amputations are performed when arterial perfusion is in question.

Hip Disarticulation

Lower extremity amputation at the level of the hip is an uncommon operation. The indications include malignancy, trauma, and infection and, rarely, because of complications of arterial insufficiency. Hip disarticulation performed for an ischemic AKA is often associated with complications in the absence of revascularization.³⁴ This technique is well described.

Cryoamputation

Rarely, a patient may require an emergent amputation yet have overwhelming medical problems that preclude any operative intervention. In this situation, a temporizing cryoamputation (aka, medical or physiologic amputation) is indicated.¹⁴ A tourniquet is placed proximal to the infectious or gangrenous process and the extremity is packed in dry ice. This prevents the systemic release of muscle degradation products and allows the required procedure to be delayed while the patient's condition can be stabilized. This technique can be performed at any level on the extremity. Consideration of the level of tourniquet application is extremely important to preserve as much viable tissue as possible and avoid higher levels of limb loss. The dry ice should be placed about 3 inc below the tourniquet to reduce the chance of the "freeze line" extending proximal to the tourniquet. Adequate pain management should always be employed.

It should be noted that the use of cryoamputation constitutes a commitment to eventual surgical amputation (primary or staged). Once initiated, maintenance of the physiologic amputation is vital until definitive surgical removal is possible. As the frozen tissues thaw, a systemic inflammatory response syndrome (SIRS) or sepsis with hemodynamic instability may occur as inflammatory mediators are liberated back into the circulatory system. The ideal timing to proceed to the operating room would be as soon as reasonably possible. However, the literature describes the successful maintenance of this technique over many days if necessary.^{14,35,36}

Other Lower Extremity Amputations

Three additional partial-foot amputations have been well described. A Lisfranc amputation is performed at the tarsometatarsal joint level and may be an option if there is inadequate soft tissue coverage for a TMA.³⁷ A Chopart amputation is performed at the level of the calcaneocuboid–talonavicular bones. Consideration of adding a percutaneous heel-cord lengthening with these amputations has been recommended.³⁸ A partial calcaneotomy hindfoot amputation has shown good utility for chronic posterior heel wounds and calcaneal osteomyelitis.^{39,40} This amputation involves removal of the posterior body of the calcaneus behind the posterior facet of the subtalar joint. Primary closure is typically possible and patients can ambulate following this procedure using a custom orthotic with a heel filler. Knee disarticulation is a useful amputation for patients with immature growth plates. It is superior to an AKA and allows end-weight-bearing, improved proprioception, and improved prosthetic

control. The required prosthesis is bulky and less cosmetically appealing than that used for a BKA. The technique is well described.⁴¹ Rotationplasty is an uncommon procedure performed primarily for treatment of osteogenic sarcoma of the thigh.⁴² It involves nerve-sparing resection of the femur and knee, 180-degree rotation of the leg, and reattachment of the leg. This results in a functional, sensate foot that can easily be fit with a prosthesis.

Wound Dressings

An important consideration after amputation is the type of wound dressings applied to the stump. Two important factors in the success of an amputation are time-to-rehabilitation and complete wound healing, both of which are influenced by postoperative wound care.⁴³ With transtibial amputations, there are a number of options, such as soft gauze dressings with elastic wrap, rigid plaster dressings without immediate prosthesis, rigid plaster with immediate postoperative prosthesis, and prefabricated pneumatic postoperative prosthesis. Several studies have compared two or more of these options. Endpoints are not standardized, however, and most studies are not randomized and prospective, making comparisons and meta-analysis difficult.⁴³

Benefits and drawbacks are found for each postoperative option.⁴³ Gauze dressings with elastic wrap are simple and low cost and provide good accessibility to evaluate wound healing. On the other hand, they may lead to higher rates of joint contraction, increased time to ambulation, and risk pressure ischemia from poorly placed elastic wrap. Despite these drawbacks, no convincing data show that soft gauze dressings are inferior to other options.^{43,44} A removable knee immobilizer may be used in conjunction with gauze dressings to minimize the risk of joint contracture.

Rigid plaster casts help with joint contracture and protect the wound from trauma. With addition of a temporary prosthesis, the rigid plaster also promotes early ambulation. The plaster, however, does not provide easy access to evaluate and care for the wound and if not fitted properly will result in sheer stress and thereby break down the wound. Consequently, a level of skill in plaster placement is required of the surgical team to make appropriate and often frequent plaster changes.⁴³

Finally, a prefabricated pneumatic postoperative prosthesis allows early ambulation and weight bearing, easy wound access for examination, prevention of joint contracture, and wound protection. The prosthesis, however, is bulky and upfront is more expensive than the simple gauze. Prospective studies have demonstrated statistically fewer postoperative complications with the pneumatic prosthesis and statistically fewer limbs requiring higher revisions.⁴⁵

RESULTS

Table 94-7 Amputation Mortality

Category	Percentage	Number
Below-knee	2	25/1,200
Above-knee	9	54/609
Diabetic vs. nondiabetic	No difference	
After amputation revision	5.5	12/218

Complications

Morbidity and Mortality

Operative mortality depends on the indication and the level. Mortality rates for major lower extremity amputations in vascular and diabetic patients have been reported to be between 0% and 35%.⁴⁶ Combined mortality rates from multiple series are shown in Table 94-7.⁴⁷ Cardiovascular causes account for two-thirds of these deaths, with myocardial infarction responsible for one-third.⁴⁷ These review data are further supported by recent studies by Sandnes et al.⁴⁸ and Aulivola et al.⁴⁹

Long-term survival following major amputation in the vascular population is shown in Table 94-8. The 5-year survival rate is only 37% compared with 85% for age-matched controls.⁵⁰

Deep Venous Thrombosis and Pulmonary Embolism

The incidence of deep venous thrombosis following lower extremity amputation ranges from 4% to 38%.⁵¹⁻⁵³ Prophylactic measures including subcutaneous heparin, low-molecular-weight heparins, early

mobilization, and pneumatic compression devices should be used as indicated.

Stump Complications

Stump complications include nonhealing, infection, hematoma, contractures, ulceration, phantom pain, and trauma. Although most amputations heal primarily, a small percentage do not. Amputation at a more proximal level usually is successful. Postoperative infections complicate 12% to 28% of all amputations with the percentage higher in cases performed for infection.⁵⁴ Local wound care with drainage, débridement and dressing changes, and systemic antibiotics should be instituted. Wound hematomas are best treated with prevention. Meticulous hemostasis and avoidance of subcutaneous cavities decrease their incidence. Hematomas should be treated in the operating room with evacuation, irrigation, and closure of the wound.

RESULTS

Table 94-8 Survival after Amputation for Ischemia

Time (y)	Survival Rate (%)
1	75
2	60
3	50
4	45
5	37

From Frang RD, Taylor LM, Porter JM. Amputations. In: Porter JM, Taylor LM, eds. *Basic Data Underlying Clinical Decision Making in Vascular Surgery*. St. Louis, MO: Quality Medical; 1994:115, with permission.

Joint contractures complicate 1% to 3% of all amputations.^{50,54} These contractures can occur rapidly postoperatively and are best treated by prevention. Rehabilitation specialists and physical therapists should evaluate patients preoperatively. Active and passive range of motion should be initiated immediately postoperatively. Adequate pain medication, ideally with patient-controlled or epidural anesthesia,^{55,56} is crucial. Pillows and bed positions that result in hip or knee flexion are to be strictly avoided.

Ulcers tend to develop over bony prominences. Poorly fitting prostheses or shoes are the most common causes. Diabetic patients with peripheral neuropathy are especially susceptible to the development of ulcers following toe and limited foot amputations. They can also form on the anterior aspect of AKAs secondary to the disproportional contraction of the hip flexors relative to the hip extensors. Local wound care and bedrest usually lead to healing if the ulcer is superficial. Deep skin ulcers with involvement of the soft tissue and the underlying bone are more complicated. They often suggest borderline perfusion of the stump and require formal revision to a higher level to treat definitively.

Another option in complicated wound closure is negative-pressure wound dressing, which has been used for a wide range of difficult-to-heal lesions. Studies indicate that this dressing technique decreases wound volume, whereas traditional moist gauze dressings do not.⁵⁷ The dressings result in granulation tissue and healing in otherwise difficult tissue beds, such as diabetic foot ulcers⁵⁸ and decubitus pressure ulcers.⁵⁹ In addition to helping contract the size of the wound, negative-pressure dressings also decrease the number and frequency of dressing changes drastically when compared with wet-to-dry dressings.

Neuromas are regenerative nerve tissues that form in response to transection. They can lead to pain if trapped in the fibrous scar or if irritated by a prosthesis. Proximal nerve division under tension during the original operation decreases the incidence of this complication. Symptomatic neuromas should be treated with proximal resection of the nerve because local excision of the neuroma is rarely adequate.

Some element of phantom extremity pain occurs in nearly all amputations,⁶⁰ although these complaints are not always directed to the treating surgeon. It is necessary to describe these common symptoms to the patient and specifically inquire about their presence. The pain is disabling in 5% to 30%⁶¹ of patients surveyed. Currently, pain is felt to be a component of a central pain syndrome and unrelated to either a neuroma or the perception of an intact extremity. Although there is no universally effective treatment, Malone⁴⁶ has reported a low incidence with an aggressive rehabilitation program, including immediate prosthetic fitting.

Trauma to a limb following an amputation can convert a healed amputation to a nonhealing wound requiring a more proximal amputation. Perioperatively, patients with a BKA have to be observed closely

to prevent attempted ambulation. Diabetic patients with retinopathy should not walk barefoot following toe and foot amputations secondary to the risk that minor trauma may lead to a major wound healing problem.

Additional Amputation

The incidence of future amputation in vascular patients is not insignificant. Snyder et al. evaluated outcomes after forefoot amputations and found that 26% underwent a subsequent forefoot amputation and 37% had a more proximal amputation over 2 years.⁶² Cruz et al. demonstrated 17% contralateral amputation in their series.⁶³ These dismal figures reflect the systemic nature of the underlying diseases and emphasize the importance of appropriate foot care, patient education, close follow-up, and early intervention.⁶⁴ A concerted multidisciplinary approach can dramatically decrease the incidence of initial and subsequent lower extremity amputation.⁶⁵

Special Situations

In selected cases, hyperbaric oxygen (HBO) therapy can provide benefit in treating nonhealing amputation sites. Patients require thorough evaluation of their cardiopulmonary status before initiating such treatment. In addition, the treating vascular surgeon has to determine that revascularization is completed or is not indicated. Patients may benefit from treatment if there is a substantial increase in transcutaneous oxygen pressure (TcPO₂) near the wound with administration of 100% oxygen. Daily treatments are typically continued for 30 days. Platelet-derived growth factor (becaplermin, regranex) is approved for use in the United States and has been effective in the management of diabetic foot ulcers and following open foot amputations or débridements. The wound must be clear of all necrotic tissue before initiating therapy.

REHABILITATION AND PROSTHETIC MANAGEMENT

General Considerations

Rehabilitation must be individualized. For some patients, successful rehabilitation means ambulation on a prosthesis and resumption of an independent lifestyle. For others, success may mean being able to pivot on the contralateral limb to be able to assist with transfer. Ambulating with a prosthesis depends on the physiologic status of the patient. Table 94-2 illustrates the dramatic increase in energy requirement with increasing level of the amputation. As expected, the chance of ambulating on a prosthesis decreases with ascending amputation level. The percentages of diabetic and vascular patients who can ambulate with amputations at various levels are shown in Table 94-9. The likelihood of ambulating postoperatively is inversely related to the patient’s age and the length of the rehabilitation process.⁶⁶ Consideration should be given to inpatient rehab immediately after the acute care of the amputation is complete. Not only does this allow strengthening of the upper extremities and improved transfers, but it has been shown to reduce 1-year mortality in amputees as well.⁶⁷

Specific Considerations

Digital and Ray Amputations

All patients who were ambulatory preoperatively should be able to achieve their preoperative functional status following a digital or ray amputation. The first digit and metatarsal head are important for weight bearing and for power. A shoe orthosis should effectively compensate for these functions when the patient has some training.

RESULTS

Table 94-9 Ambulation after Lower Extremity Amputation for Diabetes or Occlusive Disease

Amputation Level	Postoperative Ambulation (%)
Digit or ray	100
Transmetatarsal	100
Syme amputation	90–100
Below-knee	75
Above-knee	39
Hip disarticulation	<100

From Frang RD, Taylor LM, Porter JM. Amputations. In: Porter JM, Taylor LM, eds. *Basic Data Underlying Clinical Decision Making in Vascular Surgery*. St. Louis, MO: Quality Medical; 1994:155, with permission.

The most important component of postoperative rehabilitation for patients following a digital or ray amputation is education. The rate of repeat amputation (other toe, more proximal level, and contralateral limb) is extremely high. Several studies have indicated that the rate of repeat amputation is diminished with a coordinated education program.^{68,69}

Transmetatarsal Amputation

A TMA minimally increases the energy requirement of ambulation; therefore, postoperative ambulation is expected following successful healing. The absence of the toes and metatarsal heads results in the loss of some forward thrust during the push-off phase of ambulation. This deficit can be overcome with either a steel-shank or a rigid, roller-soled shoe. The void in the distal shoe is filled with an insert.

Syme Amputation

The prognosis for return to bipedal ambulation following a Syme amputation is excellent. The required energy expenditure is only 10% more than baseline.⁷⁰ A significant advantage of this amputation is the ability to ambulate on the stump with only a cup slipper. Even though this activity is permitted on only a limited basis in the home, it is much more convenient for the patient, especially when arising at night. For routine activity the patient uses a prosthesis composed of a nonmotion foot attached to a leg shaft. The shaft has a cutout on the medial aspect to allow passage of the flared distal end of the stump. The configuration of the distal end of the stump results in a bulbous ankle, which is less aesthetically pleasing than the typical below-knee prosthesis.

Below-Knee Amputation

The rehabilitation potential following a BKA is very good. Even when the indication for amputation is arterial insufficiency, approximately 75% of patients are able to ambulate with a prosthesis.⁴⁷ Multiple design options are available; however, the patellar tendon and the medial and lateral tibial flares are the weight-bearing surfaces for most prostheses. A variety of foot designs are possible to permit extension, flexion, rotation, and energy storage.

Above-Knee Amputation

Ambulation on an above-knee prosthesis is achieved by less than 40% of patients with arterial insufficiency.⁴⁷ In this patient population, the rate of ambulation on bilateral above-knee prostheses is less than 10%.⁷¹ Most above-knee prostheses use the ischial tuberosity as the primary weight-bearing surface and are secured either by a belt or a suction socket. For younger patients, a suction socket works well. Patients with groin scars from previous revascularization attempts may benefit from a belt mechanism. The knee design depends on the patient's general condition and thigh strength. A knee that engages during the stance phase of gait is more stable and is frequently used in older patients.

Chapter 95

Thoracoabdominal Aortic Aneurysms

Hazim J. Safi, Anthony L. Estrera, Charles C. Miller III, Kristofer M. Charlton-Ouw, Dianna Milewicz, and Ali Azizzadeh

Key Points

- 1 Remarkable progress has been made in the surgical treatment of thoracoabdominal aortic aneurysms.
- 2 The decline in mortality and complication rates can be attributed to improvements in surgical technique and perioperative care, particularly the adoption of adjunct distal aortic perfusion and cerebrospinal fluid drainage.
- 3 Neurologic deficit is no longer a major threat to patients, as the use of adjuncts has lowered the incidence for all thoracoabdominal aortic aneurysms to less than 2%.
- 4 Research that focuses on improving organ preservation, particularly for the most troublesome extent II thoracoabdominal aortic aneurysms, must be continued.

1 Etheredge reported the first successful repair of a thoracoabdominal aortic aneurysm (TAAA) using a homograft tube in 1955.¹ A year later, DeBakey used a Dacron tube graft to replace the descending thoracic aorta and infrarenal abdominal aorta.² Subsequently, Crawford introduced what became known as the *clamp-and-go technique*, encompassing three basic principles of aortic surgery: the inclusion technique; use of a Dacron tube graft conduit; and reimplantation of visceral and renal arteries.³ Initially, the operation to repair TAAA had to be performed with haste in order to avoid extended periods of organ ischemia. TAAA surgery has since been transformed with the use of adjuncts that provide better organ protection and improved overall outcomes. However, sudden fatal rupture of a TAAA remains a looming and unpredictable threat. Although emergency repair of ruptured TAAA can save lives, the associated morbidity and mortality remain extremely high. Elective surgical repair of TAAA is the only effective treatment for eradicating the risk of aneurysm rupture and improving patient survival (Fig. 95-1). This chapter provides a comprehensive approach to the diagnosis and management of TAAA as well as insight into the recent surgical results and advances in organ protection.

EPIDEMIOLOGY

Aortic aneurysm disease remains a significant cause of death in the United States. Improved imaging techniques, increasing mean age of the population, and overall heightened awareness all contribute to an apparent increase in the prevalence of aortic aneurysms. However, the incidence of TAAA from population studies of the thoracic or abdominal aortic aneurysms can only be inferred. Infrarenal abdominal aortic aneurysms occur three to seven times more frequently than thoracic aortic aneurysms. However, fewer than 1,000 TAAAs, aneurysms involving both the thoracic and abdominal aorta, are repaired annually, compared with approximately 50,000 infrarenal abdominal aortic aneurysms. The estimated prevalence of abdominal aortic aneurysms varies between 2.3% and 10.7%, depending on the population studied and the size used to define an aneurysm.⁴⁻⁶ The incidence of TAAAs is estimated to be 10.4 cases per 100,000 person-years.⁷ The mean age of patients with a TAAA is between 59 and 69 years with a male-to-female predominance of between 2 and 4 to 1.⁸

Fewer than 40% of patients with untreated large TAAAs survive beyond 5 years, with most deaths caused by rupture.^{3,8-10} TAAA studies have shown that rupture is more likely to occur when aneurysms exceed 5 cm in diameter and that the rate of rupture rises with increasing aneurysm size.^{9,11-14} The median size at which TAAAs rupture is around 7 cm.^{15,16} Aneurysms equal to or greater than 8 cm have an 80% risk of rupture within 1 year of diagnosis.¹⁷ The lifetime probability of rupture for any untreated aortic aneurysm is 75% to 80%, but the size at which the aneurysm will rupture and how long it will take to reach that point cannot be easily determined. However, the average overall rate of growth for TAAAs is 0.10 to 0.42 cm per year with an exponential growth rate for aneurysms exceeding

5 cm in diameter.^{11,16,18–20}

PATHOGENESIS

An aortic aneurysm is defined as a localized or diffuse dilatation that exceeds 50% of normal aortic diameter. Most TAAAs are degenerative, with an underlying pathology similar to the more frequently encountered infrarenal abdominal aortic aneurysm. Arteriosclerosis has long been implicated in the development of aortic aneurysm. However, arteriosclerosis primarily affects the intima and typically causes occlusive disease, whereas aneurysm disease usually involves the media and adventitia. Although the pathogenesis of arteriosclerotic occlusive disease and that of aneurysm disease have been shown to be distinct, the two conditions commonly occur together. Aneurysms associated with severe atheromatous disease portend the potential for poor late outcomes due to chronic occlusive branch disease and embolization. Histologically, degenerative aortic aneurysms are characterized by thinning of the media with destruction of smooth muscle cells and elastin, infiltration of inflammatory cells, and neovascularization.^{21–23} A chronic inflammatory infiltrate, comprised of macrophages, as well as T and B lymphocytes, is consistently observed in the outer layer of aneurysm wall. The degree of vessel wall inflammation varies and the stimulus for cell migration remains unclear. These inflammatory cells, particularly macrophages, secrete proteases and elastase that degrade the aortic wall. In turn, elastin degradation products may act as chemotactic agents for the influx of inflammatory cells.²¹ The role of matrix metalloproteinases (MMPs), the most prominent type of elastases, in the development of aortic aneurysms has emerged from both clinical and experimental studies. Increased elastases MMP2, MMP9, and MMP12 have been found in aortic aneurysmal aortic tissue.^{21,24–26}

Figure 95-1. Thoracoabdominal aortic aneurysm: comparison of survival rates in untreated patients versus surgically treated patients.

Many TAAAs result from chronic ascending and descending aortic dissections. Familial clustering of aortic dissections is evident because up to 20% of patients with ascending thoracic aortic aneurysms that predispose to aortic dissections have one or more first-degree relatives with the same affliction.^{27–29} Marfan syndrome, characterized by skeletal, ocular, and cardiovascular abnormalities, is the most common inherited connective tissue disorder related to aortic aneurysm and dissection. Marfan syndrome occurs at a frequency of 1:5 to 10,000 worldwide. Aortic dilatation observed in Marfan patients has been linked to mutations in fibrillin-1 protein, encoded by the *FBN1* gene. Other known genetic syndromes that predispose individuals to TAAA and dissection include Loeys–Dietz syndrome, Ehlers–Danlos syndrome, Turner syndrome, and polycystic kidney disease.^{30–33} In addition, families with multiple members who have thoracic aortic aneurysms and dissections have been reported in the literature.³⁴ In most of these families, the phenotype for TAAA and dissection is inherited in an autosomal dominant manner with marked variability in the age at onset of aortic disease and decreased penetrance.³⁴ Four genes have been identified for familial thoracic aortic aneurysms and dissections that account for 20% of this family condition. Mutations in the smooth muscle isoform of alpha-actin, encoded by *ACTA2*, are responsible for 15% of familial aortic disease. Other genes responsible for less than 2% include *MYH11*, *TGFBR2*, and *TGFBR1*.^{35–38}

A small percentage of TAAAs are the result of infection (mycotic aneurysms) or trauma (pseudoaneurysms). An infected aneurysm frequently results from bacterial or septic emboli that seed an atherosclerotic aorta. Another mechanism is contiguous spread from empyema or adjacent infected lymph nodes. Although any organism can infect the aortic wall, *Salmonella*, *Haemophilus influenza*, *Staphylococcus*, *Mycobacterium tuberculosis*, and *Treponema pallidum* spirochetes species are the most common.^{39,40} Infected aortic aneurysms are usually saccular and thought to be at greater risk for rupture. Chronic traumatic pseudoaneurysms of the aorta related to previously unrecognized traumatic transection are also prone to rupture, and surgical repair is warranted at the time of diagnosis.

Approximately 25% of TAAAs are associated with chronic aortic dissection. An estimated 20% to 40% of patients will develop aneurysms in the thoracoabdominal aorta within 2 to 5 years following acute aortic dissection.^{41–43} Persistent patency of the false aortic lumen is reported to be a significant predictor of aneurysm formation.^{42,44} However, the presence of chronic aortic dissection or patent false lumen has not been linked to a higher risk of aortic rupture.⁴⁵ Aneurysm disease occurs in more than one part of the aorta in approximately 20% of cases. The so-called “mega” aorta is an “extensive” aortic aneurysm involving the ascending, transverse arch, and the entire thoracoabdominal aorta. Although associated factors include Marfan syndrome and chronic aortic dissection, the cause of extensive aortic aneurysm remains unknown.

CLINICAL MANIFESTATIONS

Aortic aneurysms can cause compressive symptoms, although most do not until they reach a large size. The most frequent complaint is ill-defined chronic back pain, although pain can also occur in the chest, flank, or epigastrium. Acute changes in the characteristics and severity of pain can indicate sudden expansion or impending aortic rupture. Hoarseness, resulting from vocal cord paralysis caused by compression of the left recurrent laryngeal or vagus nerves, is frequently seen in patients with large aneurysms of the proximal descending thoracic aorta. Patients may also experience dyspnea related to compression of the tracheobronchial tree. A large aneurysm can exert pressure on the adjacent esophagus or duodenum, causing dysphagia or weight loss related to obstruction or early satiety. Direct erosion of the aneurysm into the adjacent tracheobronchial tree, esophagus, or both can cause exsanguination, presenting as massive hemoptysis or hematemesis, respectively. Less frequently, direct erosion can cause slow intermittent blood loss. Rarely, paraplegia or paraparesis can occur in patients with TAAA as a result of acute occlusion of the intercostal or spinal arteries. These findings are usually associated with acute aortic dissection, but can also result from thromboembolization. Although most aneurysms have a varying amount of mural thrombus, distal embolization causing acute mesenteric, renal, or lower extremity ischemia is infrequent.

Rupture is thought to be the first clinical manifestation of a TAAA in as many as 10% to 20% of patients (Fig. 95-2). The acute onset of severe chest, abdominal, or back pain associated with hypotension must raise the suspicion of a ruptured aneurysm. A pulsatile mass may be palpable in the abdomen. However, if the larger part of the TAAA is positioned deep within the thoracic cage, the aneurysm may not be apparent on physical examination. Although most ruptured aneurysms are fatal unless treated emergently, the ruptured arterial wall may temporarily seal for several hours or days before free rupture. In patients who are brought to the hospital alive, rupture is usually contained within the pleura or retroperitoneum. Free rupture is accompanied by severe hypotension and patients are more likely to die before reaching the hospital.

Figure 95-2. Computed tomography scan of a ruptured thoracoabdominal aortic aneurysm. Note stranding in the retroperitoneum denoting extravasation of blood.

Figure 95-3. Thoracoabdominal aortic aneurysm classification. Extent I, distal to the left subclavian artery to above the renal arteries. Extent II, distal to the left subclavian artery to below the renal arteries. Extent III, from the sixth intercostal space to below the renal arteries. Extent IV, the twelfth intercostal space to the iliac bifurcation (total abdominal aortic aneurysm). Extent V, below the sixth intercostal space to just above the renal arteries.

DIAGNOSTIC IMAGING

The diagnosis of TAAA can be confirmed by various imaging modalities. Currently, computed tomography angiography (CTA) is the imaging modality of choice in defining the extent of TAAA as per the modified Crawford Classification (Fig. 95-3) and for planning operative strategy. The diameter of the entire aorta, from the ascending segment to the bifurcation, can be accurately measured at various levels on axial images assuming the centerline determination is made. The distinction between the false and true lumens in aortic dissection can be shown on CTA. CTA can also detect thrombus or inflammatory changes in the aortic wall. Furthermore, the presence of free (or contained) fluid or blood can indicate free (or contained) rupture. Thin-slice CTA image acquisition can also identify patent intercostal arteries. Coronal reformatting or three-dimensional reconstruction of axial CT images provide additional views of TAAA (Fig. 95-4). These views are often helpful for surgical planning as well as determining adjacent organ involvement. Intravenous iodinated contrast can be omitted in patients with impaired renal function because it is not required for simple sizing of TAAA.

Magnetic resonance angiography (MRA) has become widely available and is frequently used as a screening test to detect diseases of the aorta and its branches. The principal advantage of MRA over

CTA is that MRA does not require intravenous iodinated contrast and, thus, can be performed safely in patients with impaired renal function. In addition, MRA avoids the radiation exposure required for CT especially when serial follow-up examinations are required. Although MRA provides better contrast resolution, its spatial resolution is poorer than that of spiral CT. In addition, CT can better demonstrate aortic calcification and intramural thrombus compared with MRA. The time required to acquire images, claustrophobia, internal metallic hardware (e.g., pacemakers or orthopedic implants), and higher cost are other limiting factors of MRA.

Figure 95-4. Somatosensory and motor evoked potentials are recorded at three sites: the popliteal fossa (A, B), C5 (C) and the vertex (D, E).

Transesophageal echocardiography (TEE) can provide excellent imaging of the ascending and descending thoracic aorta. TEE can be performed at the bedside or in the operating room. TEE can be used in patients who are too unstable to be transported to the CT scanner. TEE can show aortic wall disease, differentiating arteriosclerotic plaque from intimal tear due to dissection. In the operating room, TEE can also be used to locate the optimal area for aortic cross-clamping and to assess cardiac function. However, TEE is an invasive modality and requires an experienced operator for optimal visualization and interpretation. Examination of the aorta by TEE is limited to the supradiaphragmatic aorta because the ultrasound probe loses contact with the aorta as it crosses the gastroesophageal junction.

Intravascular ultrasound has become an important diagnostic modality in thoracic aortic disease as it allows very good characterization of the intraluminal relationships, especially in aortic dissection. Although relatively invasive, requiring arterial sheath access, this is becoming an important modality for planning endovascular therapies in aortic dissection. Epiaortic ultrasound has also been applied to TAAA treatment. Epiaortic ultrasound can allow better characterization of the thoracic aorta for cannulation or clamping.

PREOPERATIVE EVALUATION

The initial consultation with the TAAA patient focuses on a thorough history and physical examination, primarily to detect comorbidities, because there are generally few symptoms or physical signs related to the aneurysm itself. The extent of the TAAA is determined from imaging studies. Further evaluation of associated risk factors is performed, and consultation with a cardiologist, pulmonologist, or nephrologist is often necessary to aid in the stratification of risks.

Ischemic heart disease is prevalent in this population and is the most common cause of death in patients with a TAAA. TEE provides an excellent estimate of cardiac function. Coronary artery revascularization for critically stenosed coronary artery disease, using either percutaneous intervention (balloon angioplasty or stent) or surgical bypass, may be indicated prior to TAAA surgery, but the risk of rupture of the aneurysm must be weighed against the risk of coronary intervention and the delay caused by intervention. For patients who must undergo coronary artery bypass prior to TAAA repair, the conduit of choice is the saphenous vein graft. Use of the left internal mammary artery is avoided to prevent potential cardiac ischemia if aortic cross-clamping proximal to the left subclavian artery is required during the TAAA repair. Moreover, the internal mammary artery may be an important

collateral blood supply to the spinal cord and chest wall.

Although percutaneous coronary intervention may be considered, the use of either bare metal stents or just balloon angioplasty is preferred over drug-eluting stents since drug-eluting stents require long-term administration of clopidogrel to prevent stent thrombosis. Fortunately, medical management can be adopted for most cases of mild-to-moderate coronary artery disease and in cases of severe disease that is asymptomatic with preserved ejection fraction. Patients who develop symptoms from critical disease, for example, left main or ostial left anterior descending coronary occlusive disease, should probably have this addressed prior to aneurysm repair. In very rare situations, combined and simultaneous coronary artery bypass and TAAA repair may be considered.

OPERATIVE TECHNIQUES

The patient is brought to the operating room and placed in the supine position on the operating table and prepared for surgery. The right radial artery is cannulated for continuous arterial pressure monitoring. General anesthesia is induced. Endotracheal intubation is established using a double-lumen tube for selective one-lung ventilation during surgery. A sheath is inserted in the internal jugular vein, and a pulmonary balloon-tipped catheter is floated into the pulmonary artery for continuous monitoring of the central venous and pulmonary artery pressures. Large-bore central and peripheral venous lines are established for fluid and blood replacement therapy. Temperature probes are placed in the patient's nasopharynx and bladder. Electrodes are attached to the scalp for electroencephalography and along the spinal cord for both motor- and somatosensory-evoked potential (MEP and SSEP) to assess the central nervous system and spinal cord function, respectively (Fig. 95-5). The patient is then positioned on the right side with the hips and knees flexed to open the intervertebral spaces. A lumbar catheter is placed in the third or fourth lumbar space to provide cerebrospinal fluid (CSF) pressure monitoring and drainage (Fig. 95-6). The CSF pressure is kept at 10 mm Hg or less by gravity drainage of CSF throughout the procedure. The patient is then repositioned in the right lateral decubitus position with the hips slightly turned to allow access to both groins. The operative field is scrubbed using standard aseptic solution and draped.

Figure 95-5. Sagittal computed tomography image of an extent II TAAA.

Figure 95-6. Placement of the lumbar catheter in the third or fourth lumbar space to provide cerebrospinal fluid drainage and pressure monitoring.

The incision is tailored to complement the extent of the aneurysm (Fig. 95-7). The full thoracoabdominal incision begins posteriorly between the tip of the scapula and the spinous process, curving along the sixth intercostal space to the costal cartilage, and then obliquely to the umbilicus. The latissimus dorsi muscle is divided and the insertion of the serratus anterior muscle is mobilized. The left lung is deflated and the left thoracic cavity is entered. Usually, a full thoracoabdominal exploration is necessary for extent II, III, and IV TAAAs. A modified thoracoabdominal incision begins similar to the full thoracoabdominal incision, but ends at the costal cartilage. The modified thoracoabdominal incision provides excellent exposure for surgery involving the descending thoracic aorta, extents I and V TAAA when the aneurysm ends above the renal arteries. A self-retaining retractor is placed firmly on the edges of the incision to maintain full thoracic and abdominal exposure during the procedure.

The dissection begins at the level of the hilum of the lung cephalad to the proximal descending thoracic aorta. The ligamentum arteriosum is identified and transected, taking care to avoid injury to the left recurrent laryngeal nerve. The extent of the distal abdominal aneurysm is assessed. Only the muscular portion of the diaphragm is divided and the left phrenic nerve preserved (Fig. 95-8). A retroperitoneal plane is then developed, mobilizing the spleen, bowel, and left kidney to the right side of the abdominal aorta (medial visceral rotation). To prepare for distal aortic perfusion, the patient is anticoagulated using intravenous heparin (0.5 to 1 mg/kg body weight). The pericardium is opened posterior to the left phrenic nerve to allow direct visualization of the pulmonary veins and left atrium. The left inferior pulmonary vein is cannulated. A centrifugal pump with an inline heat exchanger is attached to the outflow cannula and the arterial inflow is established through the left common femoral artery via a Dacron graft sutured to the common femoral artery in an end-to-side fashion, or the descending thoracic aorta, if the femoral artery is not accessible. The end-to-side fashion prevents ischemia to the left leg that may be associated with renal dysfunction. Distal aortic perfusion is begun (Fig. 95-9).

Padded clamps are applied to the proximal descending thoracic aorta just distal to the left subclavian artery and the midthoracic aorta. When the proximal extent of the aneurysm is too close to the left subclavian artery, the aorta between the left common and left subclavian arteries is clamped. The left subclavian artery is clamped separately. Because of the danger of graft–esophageal fistula, the inclusion technique for the proximal anastomosis is no longer used. Instead, the aorta is transected to separate it from the underlying esophagus (Fig. 95-10A). A woven Dacron graft impregnated with collagen or gelatin for replacement is preferred. The graft is sutured in an end-to-end fashion to the descending thoracic aorta, using a running 2-0 or 3-0 monofilament polypropylene suture. The anastomosis is checked for bleeding. Pledgeted polypropylene sutures for reinforcement are placed, if necessary. Sequential clamping is used for all TAAAs. After completion of the proximal anastomosis, the middescending aortic clamp is moved distally onto the abdominal aorta at the celiac axis to accommodate intercostal reattachment. Reattachment of patent, lower intercostal arteries (T8 to T12) is performed, except in cases of occluded arteries, heavily calcified aorta, or acute aortic dissection, guided by the neuromonitoring, that is, MEPs and SSEPs. If no changes are noted in the neuromonitoring of the spinal cord, then patent intercostal arteries can be ligated without fear of spinal cord injury. If intercostal reattachment is performed, the proximal clamp is released from the aorta and reapplied on the aortic graft beyond the intercostal patch, restoring pulsatile flow to the reattached

intercostal arteries (Fig. 95-10B). The distal clamp is moved onto the infrarenal aorta, the abdominal aorta is opened, and the graft is passed through the aortic hiatus. The celiac, superior mesenteric, and renal arteries are identified and perfused using 9- or 12-Fr balloon-tipped catheters, depending on the size of the ostia (Fig. 95-10C). The delivery of cold perfusate (4°C) to the viscera depends on the proximal aortic pressure, which is maintained between 300 and 600 mL/min. Renal temperature is directly monitored and kept at approximately 15°C. The visceral vessels are usually reattached using the inclusion technique. On completion of this anastomosis, the proximal clamp is moved beyond the visceral patch, restoring pulsatile flow to the viscera and kidneys (Fig. 95-10D). The final graft anastomosis is then completed at the aortic bifurcation. In most cases, an island patch accommodates reattachment of the celiac, superior mesenteric, and both renal arteries. If the right or left renal artery is located at too great a distance from other arteries, its reattachment usually requires a separate interposition bypass graft. A visceral patch is no longer used for patients with connective tissue disease (Marfan) and in patients younger than 60 years because of the high incidence of recurrent patch aneurysms in such cases. Instead, a woven Dacron commercially available graft is used with side-arm grafts of 10 mm and 12 mm for separate attachment of the celiac, superior mesenteric, and the left and right renal arteries. Similarly, in these patients, a loop graft has replaced the island patch for reattachment of the intercostal arteries.

Figure 95-7. Tailoring of thoracoabdominal incisions for aneurysm extent. DTAA, descending thoracic aortic aneurysms; TAAA, thoracoabdominal aortic aneurysm; SMA, superior mesenteric artery.

Figure 95-8. In previous surgical practice, the diaphragm was divided (A); currently, only the muscular portion of the diaphragm is cut (B).

Figure 95-9. Distal aortic perfusion from the left inferior pulmonary vein to the left common femoral artery.

Figure 95-10. Sequential clamping and graft replacement. Padded clamps are placed on the proximal and mid-distal descending thoracic aorta. **A:** The proximal part of the aneurysm is opened. The aortic neck is completely transected and separated from the

esophagus. The proximal anastomosis is fashioned. Subsequently, the patent lower intercostal arteries are reattached via an elliptical hole in the graft. **B:** The proximal clamp is then moved onto the graft to restore pulsatile flow to the intercostal arteries, and the graft is pulled through the hiatus into the abdomen. The distal clamp is reapplied onto the infrarenal aorta. The remainder of the aneurysm is opened. Balloon-tipped catheters are inserted into the celiac, superior mesenteric, and renal arteries to permit perfusion. **C:** An elliptical hole is made in the graft for reimplantation of the visceral and renal arteries.

The patient is weaned from partial bypass once the core body or nasopharyngeal temperature reaches 36°C. Protamine is administered (1 mg/1 mg heparin), and the atrial and femoral cannulae are removed. Once hemostasis is achieved, two or three 36-Fr chest tubes are placed in the pleural cavity for drainage. The diaphragm is reapproximated using running 1-0 polypropylene suture. The left lung is reinflated. Closure of the incision is done in a standard fashion. The patient is placed in the supine position and a single-lumen endotracheal tube is exchanged for the double-lumen tube. If the vocal cords are swollen, the double-lumen tube is kept in place until the swelling resolves. The patient is then transferred to the intensive care unit (ICU). [Figure 95-11](#) shows an extent II TAAA before and after surgery.

Elephant Trunk Technique for Extensive Aortic Aneurysms

Single-stage repair of extensive aneurysms involving the ascending, arch, and thoracoabdominal aorta greatly increases operative risks. The patient undergoes a lengthy procedure that requires multiple incisions, a daunting array of protective surgical adjuncts, protracted clamp times, and considerable blood loss. Staged repair is a practical solution. Prior to the introduction of the elephant trunk technique by Borst⁴⁶ in 1983, staged repair was fraught with complications, particularly excessive bleeding from the pulmonary artery and thoracic aorta in the second-stage repair of the thoracic or thoracoabdominal aorta. The elephant trunk technique resolves this problem because it allows the surgeon to avoid surgical manipulation and cross-clamping the proximal native descending thoracic aorta in the second stage.

The first stage of the elephant trunk technique is performed in a similar fashion to standard surgery of the ascending aorta and transverse arch, with the exception that either an inverted distal graft or a commercially available collared graft is inserted distally ([Fig. 95-12A](#)). The folded edge of the inverted graft or the collared portion of the elephant trunk graft is sutured to the descending thoracic aorta just distal to the left subclavian artery. When the distal anastomosis is completed, the inner portion of the inverted graft is retrieved. A side hole is made in the graft, and the aortic island containing the great vessels is reimplanted. The proximal anastomosis to the ascending aorta is completed, and the distal portion of the graft, or “elephant trunk,” is left dangling in the proximal descending aorta. In the first stage, cardiopulmonary bypass, profound hypothermia, circulatory arrest, and retrograde cerebral perfusion provide protection to the brain and guard against stroke.

The second stage of the elephant trunk technique is much like standard TAAA repair, using the adjuncts distal aortic perfusion and CSF drainage. After initiation of the pump, the distal clamp is applied at the mid-descending thoracic aorta. The proximal third of the descending thoracic aorta is opened without a proximal clamp. The elephant trunk portion of the graft, inserted in the descending thoracic aorta during stage 1, is grasped quickly and clamped ([Fig. 95-12B](#) and [C](#)). The new graft is sutured to the “elephant trunk” to replace the remaining aneurysm.

Figure 95-11. Example of TAAA extent II repair. (A) Preoperative computed tomography showing proximal part of the aneurysm with chronic dissection. Intraoperative photograph of the thoracoabdominal aortic aneurysm before (B) and after (C) graft replacement. The proximal anastomosis was just distal to the left subclavian artery; the patent lower intercostal arteries were reattached; the celiac, superior mesenteric and right renal arteries were reimplanted together; the left renal artery was reimplanted via an interposition bypass graft; and the distal anastomosis was to the aorta just above the bifurcation. The separate left renal artery graft was necessary because it was located far away from the remaining visceral arteries.

Figure 95-12. Elephant trunk technique. Illustration of completed stage 1 elephant trunk (A). In stage 2, the proximal aneurysm is opened and the existing graft is quickly grasped (B) and clamped (C). The remainder of the surgery follows the standard technique

POSTOPERATIVE MANAGEMENT

In the ICU, the patient's hemodynamic status is monitored very closely. The patient is awakened as quickly as possible to check neurologic status. Most patients may be extubated within hours of arriving to the ICU assuming swelling is minimal and hemodynamics are stable. Blood loss is liberally replaced using banked blood products. The patient's mean arterial pressure is maintained between 80 and 90 mm Hg to ensure adequate organ perfusion, particularly to the spinal cord. CSF pressure is continuously monitored. Approximately 10 to 15 mL of CSF is drained hourly to keep CSF pressure at 10 mm Hg or less. Ideally, the patient is weaned off the ventilator on the first postoperative day. Oral diet is resumed when the patient is extubated and has bowel sounds.

After the patient recovers from anesthesia and is moving all extremities, potential delayed neurologic deficit (DND) is monitored. Warning signs for DND include unstable arterial blood pressure, hypoxemia, low hemoglobin (<10 g/dL), or increased CSF pressure (>15 mm Hg). CSF drainage is discontinued on the third postoperative day. The length of stay in the ICU is about 3 to 4 days, depending on the neurologic and pulmonary status of the patient.⁴⁷ The patient is subsequently transferred to the telemetry floor. Physical therapy is initiated in the ICU and continued throughout the patient's hospital stay.

Annual CT scan follow-up is recommended to screen for the development of new aneurysms or graft-related pseudoaneurysm formation. The frequency of follow-up visits or CT scans varies based on TAAA etiology. For example, patients with remaining unoperated aortic dissection, connective tissue disorders (Marfan syndrome), family history of aortic aneurysm, or concurrent aneurysms may need closer surveillance.

SURGICAL OUTCOMES

2 Mortality rates for patients undergoing TAAA and descending thoracic aortic aneurysm repair range between 4% and 21%.^{12,48–51} The variable success rates are partly related to the heterogeneity of the patient population and the expertise of the treating team. In the cumulative experience of the authors of this chapter (January 1991 to July 2012), 1,511 patients underwent TAAA and descending thoracic aortic aneurysm repair. Of these patients, 64% were men with a median age of 67 years (range, 8 to 91 years). Approximately 7% of patients had emergency surgery for free or contained rupture of TAAA or descending thoracic aortic aneurysm. Currently, the 30-day mortality rate is approximately 15%, but patients with normal renal function, that is, with calculated glomerular filtration rate (GFR) >90 mL/min/1.73 m², the early mortality was 5.9%. Using multivariable analysis, advanced age, renal failure, and paraplegia have been identified as important risk factors for mortality.⁵² Overall, 70% of patients recover from TAAA without significant postoperative complications.⁵³ The 5-year survival for patients after TAAA is between 60% and 70%. Recently, negative predictors for long-term survival were found to include advanced age, extent II TAAA, renal failure, emergency surgery, cerebrovascular disease, and active tobacco smoking.⁵²

Neurologic Outcomes

3 Postoperative neurologic deficit remains the most devastating complication following TAAA repair. When the descending thoracic aorta is cross-clamped, the spinal cord is quickly rendered ischemic because of the immediate interruption of perfusion to the spinal cord and consequent increased CSF pressure. Therefore, in the “cross-clamp-and-go” era, the single most important predictor of neurologic deficit was the length of clamp time. The rationale for the present method of protection is to increase the spinal cord perfusion pressure directly with distal aortic perfusion, and indirectly by reducing CSF pressure to 10 mm Hg or less. Animal and human studies have confirmed that CSF drainage reduces CSF pressure and can improve spinal cord perfusion during aortic cross-clamping.^{54–56}

The adjuncts, distal aortic perfusion and CSF drainage with moderate hypothermia, were used in 1,155 of 1,511 (76%) patients. In our cumulative experience, the use of combined adjunct distal aortic perfusion and CSF drainage has been associated with a 44% reduction in the odds of neurologic deficit across all aneurysm extents. That is, the overall incidence of neurologic deficit for all patients

without the use of adjunct was 4.5%, whereas it was 2.5% for those with adjunct. While aortic cross-clamp time remains a major predictor of paraplegia when plotted on a continuum, the curve has shifted to the right with longer ischemic tolerance provided by the adjuncts. In high-risk extent II aneurysms, adjuncts reduced neurologic deficit from 30% to 9% at the average aortic cross-clamp time of 75 minutes (Fig. 95-13). When all aneurysm extents are modeled together with nonadjunct cases excluded, use of adjuncts has pushed the rates down to the range of 1% to 5% and vastly increased clamp time tolerance. This combination of results has made the current statistical models insensitive to cross-clamp time, so that although the intercept for extent II aneurysms is greater, the estimates for all extents are flat across clamp time (Fig. 95-14). Clearly, the adoption of adjunct has impacted the overall incidence of neurologic deficit, and this has led us to recategorize “low” versus “high” risk, as “extent non-II” versus “extent II.”⁵⁷

Figure 95-13. In extent II aneurysms, the probability of developing neurologic deficits increases with increasing clamp time, but the use of adjunct distal aortic perfusion and CSF drainage reduces the chances of neurologic deficit by prolonging ischemic tolerance.

Figure 95-14. For thoracoabdominal aortic aneurysms and all other aneurysms, the use of adjuncts has made the probability of neurologic deficits low and unrelated to cross-clamp time.

Since 1991, distal aortic perfusion and CSF drainage have been utilized as adjuncts for all patients undergoing elective repair of TAAA. Overall, in a total of 1,004 patients, immediate postoperative neurologic deficit (paraplegia or paraparesis that occurs as the patient awakens from anesthesia) occurred in 2.4% of patients operated with adjuncts, and in 6.8% patients without adjuncts.⁵² This combination of adjuncts has reduced the cumulative rate of neurologic deficits to 0.9% for descending thoracic aortic repair and to 3.3% for thoracoabdominal aortic repair.⁵² Repair of the most extensive TAAAs (extent II) has long been known to result in the highest incidence of neurologic deficits. In the cross-clamp-and-go era, this incidence was as high as 30% to 40%.⁵⁰ With the use of adjuncts, the rate of immediate neurologic deficits for extent II TAAA has been reduced to 7.2%⁵² (Fig. 95-15). In addition to the extent of the aneurysm, other perioperative risk factors for

immediate neurologic deficits include age, emergency presentation, renal dysfunction, active smoking, and cerebrovascular disease. The use of intraoperative distal aortic perfusion and perioperative CSF drainage, in combination, prevents 1 neurologic deficit in 20 cases for all patients, and 1 in 5 for extent II TAAA.⁵²

Figure 95-15. The probability of neurologic deficit increases with clamp time and is markedly higher in patients undergoing thoracoabdominal aortic aneurysm surgery without adjuncts.

Also important in spinal cord protection is the reimplantation of intercostal arteries. During the era of cross-clamp-and-go reimplantation of intercostal arteries was found to be a risk factor for postoperative neurologic deficit.⁵⁸ This link was explained by the longer cross-clamp time required to reattach the intercostal arteries. The level at which the anterior radicular artery, known as the *artery of Adamkiewicz* or *arteria radicularis magna*, originates is known to be variable. Most commonly, this artery branches from one of the lower intercostal arteries with or without additional collateral branches from nearby intercostal arteries. The anterior radicular artery is believed to be the major blood supply to the anterior spinal artery of the spinal cord. The relationship of neurologic deficit to ligation, reimplantation, and pre-existing occlusion of intercostal arteries in patients undergoing TAAA repair using adjuncts has been studied. It was found that ligation of patent lower intercostal arteries (T9 to T12) increased the risk of paraplegia.⁵⁸ Therefore, all patent lower intercostal arteries from T9 to T12 are reattached, either together as a patch to a side hole made in the Dacron graft or, when the intercostal arteries are too far apart, separately as buttons or using interposition bypass grafts. However, if the lower intercostal arteries are occluded, the patent upper intercostal arteries will be reimplanted, because these are thought to assume a more important role in the collateral system to the anterior spinal artery in this situation.

Adequate spinal cord perfusion pressure should be maintained with avoidance of hypotension during and after surgery. Intravenous nitroprusside, in particular, can precipitate systemic hypotension, and has been shown to cause a paradoxical increase of CSF pressure.⁵⁹ Therefore, it is no longer used. A detailed account of the essential anesthetic care during TAAA repair is beyond the scope of this chapter. However, the importance of adequate maintenance of systemic arterial pressure with judicious blood transfusion cannot be overemphasized, as organ perfusion greatly depends on the systemic circulation. Clearly, the era of cross-clamp-and-go is over and the spinal cord must be provided with some form of protection.

Cord function can be assessed using intraoperative neurophysiologic monitoring with MEPs and SSEPs as performed routinely in aortic surgery.^{60,61} For SSEP, probes are placed at the malleolus bilaterally, stimulating the posterior tibial nerve. Recordings are performed at three sites (Fig. 95-4), including the popliteal fossa, C5, and the vertex with a positive finding defined as a drop in amplitude by 50% and/or a change in latency by 10%. For MEP, precentral gyrus is stimulated and recording is measured at three sites, including the abductor digiti minimi, tibialis anterior, and abductor hallucis muscle. Compound muscle action potential is monitored with a positive finding defined as an all-or-none potential. If there are signal changes, as defined earlier, intraoperative corrective measures are performed, which include increasing the mean central pressure to more than 80 mm Hg, increasing distal aortic perfusion pressure to more than 60 mm Hg, lowering the CSF pressure, increasing the hemoglobin level, and attaching additional intercostal arteries. With the

current use of adjunct therapy and intraoperative SSEP and MEP monitoring, the current rate of immediate neurologic deficit remains at 3.1%.⁶²

Delayed Neurologic Deficits

DND refers to the onset of paraplegia or paraparesis after a period of observed normal neurologic function. Delayed-onset neurologic deficit after TAAA repair was first reported in 1988, at which time the condition was considered irreversible and beyond the surgeon's control.⁶³ Since then, numerous reports have described improvements in patients neurologic function by using CSF drainage for delayed-onset neurologic deficits.^{64–66} DND has been observed as early as 2 hours and as late as 2 weeks following surgery (median, 3 days), in 2.7% of patients.⁶⁷ No single risk factor is responsible for DND. However, using multivariable analysis, acute dissection, extent II TAAA, and renal insufficiency were identified as significant preoperative predictors for delayed-onset neurologic deficit.⁶⁷ In a subsequent case-control study, postoperative mean arterial pressure of less than 60 mm Hg and CSF drain complications were found to be predictors in the development of delayed-onset neurologic deficit, independent of preoperative predictors (Fig. 95-16).⁶⁸

Figure 95-16. Odds of delayed neurologic deficit by lowest postoperative mean arterial blood pressure, with or without cerebrospinal fluid drain complication. Odds are referenced to one. For example, a patient with a mean arterial blood pressure of 40 mm Hg and a cerebrospinal fluid drain complication would have 40:1 odds of delayed neurologic deficit.

As improved spinal cord protection during TAAA surgery has reduced the incidence of neurologic complications, delayed-onset neurologic deficit has emerged as an important clinical entity. The exact mechanisms involved in the development of DND remain unknown. It is speculated that DND after TAAA repair may result from a “second hit” phenomenon. Adjuncts can protect the spinal cord intraoperatively and reduce the incidence of immediate neurologic deficit, but the spinal cord remains vulnerable during the early postoperative period. Additional ischemic insults caused by hemodynamic instability, malfunction of the CSF drainage catheter, or both may constitute a “second hit,” causing DND. Furthermore, in the rigid, unyielding spinal column, any rise in CSF pressure could lead to an increase in compartment pressure, with consequent decreased spinal cord perfusion. Hence, CSF is drained freely when DND develops to relieve the compartment pressure.

To optimize postoperative spinal cord perfusion and oxygen delivery, mean arterial pressure is kept above 90 to 100 mm Hg, hemoglobin above 10 mg/dL, and cardiac index greater than 2.0 L/min. If DND occurs, measures to increase spinal cord perfusion are instituted immediately. The patient is placed flat in the supine position. The patency and function of the drain is ascertained at once. If the drain has been removed, the CSF drainage catheter is reinserted immediately and CSF is drained freely until the CSF pressure drops below 10 mm Hg. The systemic arterial pressure is raised, blood transfusion is liberally infused, and oxygen saturation is increased, as indicated above. CSF drainage is continued for at least 72 hours for all patients with delayed-onset neurologic deficit. Using this multifaceted approach to treating delayed-onset neurologic deficit, an improvement in neurologic function is seen in 57% of patients.⁶⁷ When the CSF drain was still in place at the onset of DND, 75% of patients recovered function; 43% recovered neurologic function if the CSF drain had to be reinserted at the time of the DND. Patients who developed DND but did not have CSF drainage failed to recover function.

Renal Failure

Acute postoperative renal failure is defined as an increase in serum creatinine of 1 mg/dL per day for 2 consecutive days or by the need for hemodialysis. The reported rate of acute renal failure from large series of patients undergoing TAAA repair falls within the range of 5% to 40% and is associated with mortality rates as high as 70%. Patients who develop acute renal failure more frequently sustain nonrenal complications, such as respiratory failure, central nervous system dysfunction, sepsis, and gastrointestinal hemorrhage. For patients who develop postoperative renal failure, early continuous venovenous hemodialysis or daily intermittent hemodialysis is initiated. In the experience of the authors of this chapter, approximately one-third of patients who develop acute renal failure remain on hemodialysis and, predictably, these patients have a prolonged length of hospital stay. Long-term survival for patients on hemodialysis is dismal. Preoperative chronic renal insufficiency and ruptured aneurysms are known predictors of acute postoperative renal failure. Although the authors of this chapter have theorized that patients with the most extensive extent II TAAA are at highest risk for the development of postoperative renal failure, extent of TAAA has not been shown to be a significant predictor.

The goals of perioperative renal protection are to maintain adequate renal oxygen delivery, reduce renal oxygen utilization, and reduce direct renal tubular injury. However, good strategies to protect renal function during surgical TAAA repair remain elusive. The benefit of cold temperatures for metabolic suppression in organ protection is well known. Local hypothermia has been shown to protect against renal ischemia and reperfusion injury in laboratory animals, and there is some evidence that patients with cold visceral perfusion have superior survival and recovery rates. However, this strategy has not decreased the incidence of acute renal failure. The incidence of postoperative renal failure remains troublesome and the pursuit of an optimal method of renal protection continues to be a top priority.

Glomerular Filtration Rate

4 Clinically apparent renal insufficiency is a known predictor of 30-day mortality. The overall 30-day mortality was 227 of 1,511 (15%), and the 5-year survival rate was 54%. Increasingly, we are finding that mortality cannot properly be interpreted without knowledge of preoperative GFR. With normal GFR (>90 mL/min/1.73 m²), 30-day mortality was 6%, whereas 5-year survival was 77%. With a decline in GFR to the 65 to 90 range, 30-day mortality was 8.9%. Below a GFR of 65, 30-day mortality increases to 22%. Long-term survival stratified by quartile of GFR is shown in Figure 95-17. The effect of GFR on both short-term mortality and long-term survival was highly statistically significant ($p < 0.0001$ for both measures).

Recently, in patients undergoing TAAA repair without apparent renal disease, we have found that calculated GFR is a much stronger predictor for mortality than serum creatinine.⁶⁹ We have used and appraised many different forms of renal protection, including distal aortic perfusion, warm blood visceral perfusion, antegrade cold blood visceral perfusion, retrograde cold blood perfusion, and the perioperative use of a renal protective pharmacologic agent, fenoldopam. None of these yielded overly promising results. Using multivariable analyses, we found that preoperative renal failure (creatinine >2.8 g/dL), left renal artery reattachment, visceral perfusion, and clamp-and-sew technique are predictors of acute renal failure.⁵⁷

Figure 95-17. Long-term survival stratified by quartile of glomerular filtration rate.

In the past, we had used visceral perfusion without cooling or systemic heparin, and this was likely the reason for the negative effect of visceral perfusion on renal protection. We recently reviewed the impact of various adjuncts on renal function. Distal aortic perfusion has emerged as protective but only for aortic repair that does not directly involve the renal arteries. There is evidence, however, that patients treated with cold blood visceral perfusion have superior survival and recovery rates, which may be related to improved liver protection. Thus far, none of the adjuncts evaluated have clearly prevented acute renal failure. The major predictors of postoperative renal dysfunction remain preoperative renal function, cross-clamp time, and repair extending to the renal arteries.

Excluding patients who had clinically apparent preoperative renal failure, we found that acute renal failure occurred in 344 of 1,261 (27.2%) of our patients overall. For patients with preoperative GFR above 90, renal failure was 62 of 367 (17%). When GFR was between 65 and 90, postoperative renal failure was 70 of 310 (23%). At GFRs below 65, renal failure was 212 of 584 (36%). Thirty-day mortality among patients with acute renal failure was 34% compared to 10% mortality for all other patients. Aneurysms involving the visceral vessels (extents II, III, and IV) were much more likely to produce renal failure postoperatively (39 vs. 17%, $p < 0.0001$). Approximately one-third of our patients who developed acute renal failure remained on hemodialysis, and long-term survival for patients on hemodialysis has been dismal.

Complications

A summary of complications is shown in Table 95-1. These figures are compiled from a collection of sources.⁷⁰⁻⁸⁰

Elephant Trunk Technique

The authors of this chapter have performed the two-staged elephant trunk procedure in 348 patients with extensive aortic aneurysms.⁸¹ Mortality rates range from 5% to 10% after stage one and 5% to 15% for stage two, depending on renal function. For patients with normal kidneys (GFR >90), mortality for each stage was 5%. During the interval between the two stages (approximately 31 days and 6 weeks), mortality has averaged around 6.5%, ranging from 4% to 17%, depending on why the second stage was not completed. When a 5-year follow-up of patients who failed to return for second-stage repair was performed, 32% had died. Although we were unable to determine the exact cause of death for many of these patients, it is likely that a significant number of deaths were a result of aneurysm rupture. Major complications for both stages have been relatively low, with stroke rates of 2% in the first stage and no neurologic deficits in the second. Determining the optimum length of recovery time between stages has been difficult. Because these patients are vulnerable to rupture, it is currently recommended that the second-stage repair be performed after a 4- to 6-week period of recovery.

COMPLICATIONS

Table 95-1 Complications of Open TAAA Repair

Complication	Results
Early mortality	4–21%
Immediate neurologic deficit	2–33%
Delayed neurologic deficit	2–10%
Acute renal failure – need for dialysis	2–13%
Acute renal insufficiency	6–40%
Bleeding – reoperation for bleeding	5–10%
Vocal cord paralysis/paresis and hoarseness	10%
Cardiac complication – MI, CHF	5–15%
Pulmonary insufficiency (prolonged ventilation >48 h)	10–41%
Stroke or transient ischemic attack (reversible)	2–6%
Gastrointestinal complications (pancreatitis, ischemic colitis, small bowel, cholecystitis, hepatic insufficiency)	7–10%
Chylothorax	<1%
Hospital length of stay	10–22 days
Survival	1 yr = 60–80% 5 yr = 65–80% 10 yr = 40%

CHF, chronic heart failure; MI, myocardial infarction.

Impact of Aortic Dissection

Aortic dissection has long been considered a risk factor for neurologic deficit in patients undergoing repair of descending thoracic and TAAAs, particularly during the clamp-and-go era.^{82–85} However, in a series of 729 patients operated on for descending thoracic and TAAAs, no differences were reported in neurologic outcome between those patients with and without chronic dissection. The rate of paraplegia was 3.6% with dissection versus 4.7% without dissection.⁸⁶ Several factors are likely responsible for the good neurologic outcome of patients with chronic dissection, including better surgical techniques and anesthetic care, moderate hypothermia, and reimplantation of intercostal arteries. The key element in the improved spinal cord protection; however, has been the use of the adjuncts distal aortic perfusion and CSF drainage.

In acute aortic dissection, the risk of paraplegia following graft replacement of the descending thoracic or thoracoabdominal aorta remains substantial with a neurologic deficit rate of 32%.⁸⁷ Nevertheless, acute dissection aneurysm patients are usually critically ill, undergoing surgery emergently with little time for preparation. The method of spinal cord protection employed during surgery for acute dissection is often not optimal. In particular, reimplantation of intercostal arteries is ill-advised because of the risk of catastrophic bleeding from the friable dissected tissues, and the use of the adjuncts distal aortic perfusion and CSF drainage may not be possible in the presence of hemodynamic instability.

Endovascular Repair

Since the first successful reported thoracic stent graft repair in 1994,⁸⁸ endovascular management of thoracic aortic pathology has evolved at a rapid pace. The first thoracic aortic device to receive US Food and Drug Administration (FDA) approval in the United States was the GORE TAG (WL Gore, Flagstaff, AZ) device in 2005. Since then, three additional devices, including the Valiant Thoracic (Medtronic, Santa Rosa, CA), the Zenith TX2 (Cook, Bloomington, IN), and the Relay (Bolton Medical, Sunrise, FL, USA) have received FDA approval. The benefits of endovascular therapy include decreased morbidity and mortality compared with conventional open surgery. Endovascular treatment of a TAAA would require revascularization of visceral and renal vessels. Endovascular repair is currently being performed using three different approaches, including “hybrid repair,” use of parallel grafts, and custom-made branched and fenestrated devices.

The hybrid approach requires combined open debranching of the aorta with subsequent endovascular coverage of the aneurysmal segment.⁸⁹ The debranching procedures entail an open retroperitoneal or transperitoneal approach for extra-anatomical bypassing of the visceral and renal arteries from either iliac artery. This is subsequently followed by exclusion of the thoracoabdominal aorta with stent grafts. The potential benefits of hybrid repair include the avoidance of open thoracotomy,

aortic cross-clamping, and single-lung ventilation.^{90–92} Although this approach is technically feasible, the risk of morbidity and mortality remains discouragingly high. More recent literature has suggested that the hybrid repair has no significant difference in outcomes compared to open TAAA repair.^{93–95} Indications for this approach will likely be limited to patients with TAAA who are unfit for open repair and those who are not candidates for other endovascular repair techniques (i.e., those with tortuous or inaccessible vessels, or insufficient time to order a customized stent graft).

Another approach involves the use of parallel grafts (chimneys, periscopes, or snorkels, commonly referred to as CHIMPS) to preserve blood flow to branch vessels. This technique was championed by Lobato et al. from Brazil, who reported their experience with 78 patients, 15 of whom had a TAAA.⁹⁶ Overall, they reported a technical success rate of 98.7%. Over a mean follow-up period of 17 months, the primary patency was 96.7% and early mortality was 5.1% (late: 1.3%). The reported advantages of the parallel stent grafts include the availability of a modular, off-the-shelf option that can be tailored to any anatomy.⁹⁷ This is especially useful in patients who have small and/or tortuous vessels, history of dissection, or a significant thrombus burden in the paravisceral aorta. The inherent disadvantages to this approach include potential endoleaks from the “gutters” that can lead to pressurization of the aneurysm sac. A recent systematic review of the chimney graft technique included 75 patients and a total of 96 branches, with a reported 98.9% early success rate with a perioperative mortality rate of 4%.⁹⁸

Finally, total endovascular TAAA repair can be performed using custom-made branched and/or fenestrated devices. The largest series by Greenberg et al. on their experience with 406 patients reported a perioperative mortality of 2.3% for extent IV, 5.2% for extent II and III, and 12.5% for extent I aneurysms.⁹⁹ The estimated 24-month survival was 82%, 74%, and 70% for extents IV, II and III, and I, respectively. Late complications included rupture in two patients. In a multicenter prospective study of 268 patients undergoing endovascular fenestrated and/or branched repair for juxtarenal, pararenal, and TAAA, Marzelle et al. reported 30-day mortality, inhospital mortality (IM), and combined mortality and severe complications (CMSC) rates of 6.7%, 10.1%, and 22.0%, respectively.¹⁰⁰ The authors concluded that due to the significant rate of mortality and complications, new strategies should be investigated to improve outcomes. Although significant progress has been made, the endovascular technologies continue to mature at a rapid pace. Ultimately, endovascular repair of TAAA will require modular, off-the-shelf devices that can be tailored to the variety of clinical circumstances.

ACKNOWLEDGMENTS

The authors of this chapter are grateful to G. Ken Goodrick, editor, and to Chris Akers for assistance with the illustrations.

Chapter 96

Abdominal Aortic Aneurysms

Adam W. Beck, Kristina A. Giles, and Thomas S. Huber

Key Points

- 1 An aneurysm is defined as a permanent, focal dilation of an artery that exceeds 1.5 times the normal, expected diameter.
 - 2 The risk factors for abdominal aortic aneurysm include age, male gender, smoking, family history, hypertension, chronic obstructive pulmonary disease and the presence of other aortoiliac or peripheral aneurysms.
 - 3 The diameter of an aneurysm is the greatest predictor of rupture as predicted by the tangential stress of the vessel wall.
 - 4 The natural history of abdominal aortic aneurysms is to increase in size with a mean growth rate of 0.4 cm/yr.
 - 5 The treatment of abdominal aortic aneurysm represents a balance between the risk of rupture and the operative mortality rate.
 - 6 Infrarenal abdominal aortic aneurysms should be repaired in men when their diameter reaches 5.5 cm and in women when the diameter reaches 5 cm provided they are a reasonable operative risk.
 - 7 CT arteriography is both the diagnostic study of choice and the sole imaging study required for operative planning.
 - 8 Endovascular repair is the preferred choice by both patients and providers in the United States.
 - 9 Endovascular aneurysm repair mandates long-term follow-up with serial imaging to confirm the integrity of the device and repair.
-

Abdominal aortic aneurysms (AAAs) are a common problem in developed countries and represent a significant public health concern globally. Operative repair is the only means to reduce the risk of rupture and the associated mortality. The treatment algorithm represents a balance between the risk of repair and the ongoing risk of rupture. The open technique has been the traditional approach since its description by Dubost et al.¹ in the early 1950s. The endovascular approach has emerged as the preferred treatment since its commercial release at the turn of the 21st century and has truly revolutionized the care of patients with AAAs.

DEFINITIONS AND CLASSIFICATIONS

1 An aneurysm is defined as a permanent, focal dilation of an artery that exceeds 1.5 times the normal, expected diameter.² The diameter of a normal abdominal aorta in an adult male is approximately 2 cm (range, 1.4 to 3 cm), and, therefore, a 3-cm aorta would be considered aneurysmal.³ The abdominal aorta is consistently larger in men than in women and increases slightly with age for both genders.⁴ AAAs should be differentiated from other conditions in which the size of the aorta is increased, including ectasia and arteriomegaly. In aortic *ectasia*, the diameter is increased by less than 1.5 times of the normal, expected diameter. The term *arteriomegaly* refers to a diffuse (nonfocal) enlargement of several arterial segments with increases in diameter greater than 50% of the normal expected diameter. Arterial segments in patients with arteriomegaly may be considered aneurysmal if the diameter of a segment is increased by more than 50% of the diameter of an adjacent segment. The term *aneurysmosis* denotes the presence of multiple aneurysmal segments separated by either normal, occluded, or arteriomegalic segments.

AAAs are classified primarily according to how far they extend cephalad (Fig. 96-1). More than 95% of all abdominal aortic aneurysms are classified as infrarenal.⁵ These aneurysms start below the renal arteries, and may be termed “juxtarenal” when closely approximating the renal arteries, generally less

than 10 mm along the centerline of flow below the renal orifices. AAAs classified as suprarenal extend above the renal orifices to the level of the superior mesenteric or celiac arteries. Aneurysms involving the thoracic and abdominal aorta are designated as thoracoabdominal aortic aneurysms and are classified according to how far they extend both cephalad and caudal (extent 1 through 4). Aneurysms that extend above the renal arteries are more complicated for both endovascular and open repair, and can be associated with greater morbidity. Some centers report similar outcomes for open juxtarenal and type IV thoracoabdominal aneurysm repair compared to infrarenal aneurysms; however, national results are more discrepant.⁵⁻⁷ New techniques and endograft design have expanded the indications for endovascular repair to include select juxtarenal and thoracoabdominal aneurysms.⁸⁻¹⁰

Approximately 10% to 20% of all AAAs are associated with aneurysms of the iliac arteries.^{11,12} Aneurysm involvement of the iliac vessels is usually confined to the common or internal iliac arteries, with aneurysmal involvement of the external iliac arteries being very rare. The management of AAAs associated with common iliac artery aneurysms may complicate both open and endovascular repair.

MAGNITUDE OF THE PROBLEM

AAAs and their sequelae are common problems in developed countries. The incidence of AAAs in the United States ranges from 1.5% in autopsy series to 3.2% among unselected adult patients screened with ultrasonography.¹³ Predictably, the incidence increases among subsets of patients with defined risk factors for AAAs and approximates 50% among patients with either femoral or popliteal artery aneurysms.¹³ It should be emphasized that these rates have been determined with the broad definition of an aneurysm (i.e., 1.5 times the normal vessel diameter) and do not necessarily reflect aneurysms that are of sufficient size to merit repair. Furthermore, the incidence of AAAs increased up until the end of the 20th century then has more recently plateaued and even started to decline.¹⁴⁻¹⁶ Changes in incidence may be reflective of smoking trends in the United States.¹⁷ A total of 10,597 deaths were caused by AAAs and/or dissections during 2009 and this corresponded to death rate of 3.5/100,000 as reported by the Centers for Disease Control and Prevention.¹⁸ These numbers may be underestimated because a significant number of sudden deaths in elderly patients may be secondary to undiagnosed ruptured aneurysms. Of note, spanning the time period of the introduction of endovascular AAA repair, death rates from AAA have declined by nearly 50%.¹⁹

Figure 96-1. Classification of abdominal aortic aneurysms. More than 95% of all abdominal aortic aneurysms are infrarenal. Juxtarenal aneurysms extend to the level of the renal arteries, and suprarenal aneurysms to the level of the superior mesenteric. Aneurysms extending above the superior mesenteric artery and above are designated as thoracoabdominal aneurysms and are classified (Crawford extent I–IV) according to how far they extend cephalad and caudal.

PATHOGENESIS AND RISK FACTORS

The pathogenesis of AAAs remains unresolved, although it is an intense area of both experimental and clinical investigation. Multiple potential etiologic factors have been implicated including atherosclerosis,²⁰ hemodynamics,²¹ collagen,²² collagenase,²³ elastin,²⁴ elastase,²⁵ metalloproteinases,²⁶ protease inhibitors,²⁷ programmed cell death (apoptosis),²⁸ neutrophils,²⁹ and inflammatory mediators.³⁰ The etiology is likely multifactorial with interaction between both environmental and genetic factors. Unfortunately, investigation into the potential mechanisms has not resulted in any effective biologic therapies. Elucidation of the pathogenesis has been complicated by the older age of patients at presentation and the absence of suitable animal models.

2 Multiple risk factors have been identified for the development of AAAs, including age, sex, race, smoking, hypertension, hyperlipidemia, peripheral vascular disease, myocardial infarction, and family history.^{31,32} Identification of these risk factors is important to facilitate screening high-risk patient populations. AAAs are a disease process of aging and are rare among persons less than 50 years of age. Indeed, the mean age among patients undergoing repair across the country was 75.5 years in a recent Medicare population study.¹⁹ A meta-analysis of the population-based screening studies for AAAs reported that male sex had the strongest association (odds ratio, 5.69).³³ The incidence of death resulting from AAAs for men of 60 to 64 years of age is 11-fold higher than that for women of the same age, but it is only 3-fold higher for men between 85 and 90. Furthermore, men account for approximately 80% of all AAA repairs performed nationally.^{19,34} The Aneurysm Detection and Management Veterans Affairs Cooperative Study Group (ADAM) reported that smoking was the strongest modifiable risk factor associated with AAAs >4 cm (odds ratio, 5.57) among the 73,451 veterans screened.³⁵ Similarly, Wilmink et al.³⁶ reported that abdominal aneurysms were 7.6 times more likely to develop in current smokers than in nonsmokers and that the duration of smoking rather than level of exposure appeared to correlate with their development. Decreasing prevalence of smoking has correlated with decreasing AAA deaths in the US and European population.^{17,37} Darling et al.³⁸ prospectively analyzed patients undergoing repair of AAAs and reported that 15.1% had a first-degree relative with an aneurysm, in contrast to only 1.8% in the control group. Interestingly, the presence of a female family member with an aneurysm correlated with an increased risk for rupture. Larsson et al.³⁹ reported from a population-based control study in Sweden that the relative risk of an AAA in first-degree relatives was 1.9 (95% CI, 1.6–2.2). However, the risk of an aneurysm was not affected by the gender of the index individual or relative.

The presence of an aneurysm in the aorta, iliac, femoral, or popliteal arteries dramatically increases the risk for a new or additional AAA. Metachronous aneurysms may develop anywhere in the remaining native aorta, and are commonly seen during follow-up within the residual infrarenal aortic cuff. When this occurs, the etiology of the aneurysm is often unclear and may be related to degeneration of the native aorta, or a pseudoaneurysm that develops at the anastomosis. The incidence of aortoiliac aneurysms in patients with popliteal or femoral artery aneurysms is approximately 50%.¹³ Importantly, all patients found to have one of these peripheral artery aneurysms should undergo a computed tomography (CT) scan of the entire aorta from thorax to the iliac vessels to exclude a synchronous aneurysm in addition to being screened for other peripheral aneurysms. Interestingly, the reverse scenario is not true; patients with aortic or iliac artery aneurysms have a <5% chance of having a peripheral artery aneurysm, and evaluation beyond physical examination is likely not justified.⁴⁰

The incidence of AAAs is increased among patients with an aortic dissection. Late or repeated operations are required in approximately 20% of patients by 10 years after an acute aortic dissection.⁴¹ The aneurysms may develop in either the thoracic or abdominal aorta, although the former site is more common. The term *dissecting aneurysm* is frequently used to describe fusiform degenerative aneurysms, although it is a misnomer; dissection and aneurysm degeneration are separate processes, but can occur in the setting of the other. Aneurysm false lumen degeneration can occur after a dissection, and dissection of the aorta involved in an existing aneurysm can also occur. Simply, a dissection is a tear within the aortic intima itself that leads to blood flow between the layers of the aorta (within the

media) and extends for a variable length resulting in a “true” and “false” lumen.

Interestingly, the prevalence of AAAs and the rate of expansion are both increased among heart transplant patients.^{42–44} The responsible mechanisms remain unclear, but the obligatory chronic immunosuppression may contribute. Arguments have been made to initiate screening programs as part of pre- and posttransplant evaluations.

It is notable that the risk factors for AAA are similar to those associated with the development of atherosclerosis with the noted exception of diabetes mellitus.^{45,46} Furthermore, atherosclerotic changes are found almost universally within degenerative aneurysms at the time of repair, and the two disease processes are likely related, but it is unclear how. The pathogenesis may be distinct and not necessarily causative.

PRINCIPLES OF MANAGEMENT

The treatment goals for patients with AAAs are to prolong meaningful life, relieve symptoms, and prevent rupture. Because surgical treatment is the only effective means to achieve these goals, the crucial question that must be answered is whether the patient merits repair. The decision algorithm is relatively straightforward for patients with ruptured or symptomatic aneurysms, but more difficult for patients with asymptomatic, intact aneurysms in the elective setting. The decision to recommend prophylactic intervention in the elective setting is contingent on the balance between the risk of the procedure and the risk of expectant or nonoperative management within the context of the patient’s desires or wishes and their meaningful life expectancy. Appropriate assessment of these risks requires an understanding of the size-associated risk for rupture, the growth rate, and the morbidity and mortality associated with repair, as well as the natural history of a patient with the risk factors that led to aneurysm disease.

Understanding the natural history of untreated AAA requires knowledge of the physics associated with the vessel wall. The tangential stress (t) of a fluid-filled cylindrical tube is determined by the following equation:

$$t = Pr/d$$

where P is the pressure exerted by the blood (dyne/cm²), r is the internal radius (cm), and d is the thickness (cm) of the arterial wall.⁴⁷ The tangential stress of a cylinder 0.2 cm thick with an internal radius of 0.8 cm and a fluid pressure of 150 mm Hg is 8×10^5 dyne/cm² (Fig. 96-2). An increase in the internal radius (diameter) of the cylinder to 2.94 cm and a concomitant decrease in the wall thickness, as might occur with an aneurysm, would increase the tangential stress to 98×10^5 dyne/cm². Thus, a 3-fold increase in diameter would result in a 12-fold increase in the tangential stress. Aneurysms rupture when the tangential stress exceeds the tensile strength of the vessel wall. It should be emphasized that the tangential stress varies directly with the radius of the cylinder (vessel), but is independent of its length.

3 The diameter of an AAA is the greatest predictor of rupture as would be predicted by the tangential stress of the vessel wall. The diameter of an aneurysm is determined by measuring its greatest diameter from outer wall to outer wall, preferably using an orthogonal image, throughout the extent of the aneurysm. Orthogonal refers to a cross-sectional measurement perpendicular to the long axis, along the centerline of flow to avoid overestimation due to tortuosity of the aorta. The collective annual rupture risks per aneurysm diameter are shown (Table 96-1).⁴⁸ Although there is some variability in the data, it is generally appreciated that the rupture risk for aneurysms less than 5 cm in diameter is small, but increases considerably for those greater than 5.5 cm in men and 5 cm in women. These data may be simplified by using the rule of thumb that the annual rupture risk is $\leq 5\%$ for a 5-cm aneurysm, $\sim 5\%$ for a 5.5-cm aneurysm, 10% for a 6-cm aneurysm, and 20% for a 7-cm aneurysm. These numbers correspond to an estimated 5-year rupture risk of 50% for 6-cm aneurysms and 100% for those of 7 cm. Notably, both the ADAM³⁵ and UK Small Aneurysm Trial⁴⁹ that randomized patients with small aneurysms (4 to 5.5 cm) to open repair or surveillance reported that the rupture risk for surveillance was $\leq 1\%/yr$.

Figure 96-2. Cross-sectional view of a 2-cm-diameter cylinder that expands to a diameter of 6 cm while wall cross-sectional area remains constant. t , wall stress; d , wall thickness; r_i , inside radius; r_o , outside radius. Expansion of a 1-cm-diameter cylinder to a diameter of 3 cm with no change in wall cross-sectional area increases wall tensile stress 12-fold.

A variety of other factors have also been reported to increase the risk of aneurysm rupture including female gender,^{50–52} chronic obstructive pulmonary disease,^{50,53} smoking,⁵⁰ hypertension,^{50,53} family history,⁵⁴ and wall stress.⁵⁵ The UK Small Aneurysm Trial reported that the rupture risk was increased for female gender (hazard ratio, 3), current smoking (hazard ratio, 1.5), severe COPD (hazard ratio, 0.6 per L FEV1), and higher mean arterial pressure (hazard ratio, 1.2/mm Hg). Fillinger et al.⁵⁶ used finite element analysis to calculate the wall stress of AAAs and reported that the wall stress of symptomatic/ruptured aneurysms exceeds those for elective aneurysms. The impact of the aneurysm growth rate on rupture risk remains unclear and has been difficult to separate from aneurysm diameter alone.⁵² However, an aneurysm expansion of ≥ 1 cm/yr is generally considered worrisome and a potential risk factor for rupture.

Table 96-1 Estimated Annual Rupture Risk

AAA Diameter (cm)	Rupture Risk (%/yr)
<4	0
4–5	0.5–5
5–6	3–15
6–7	10–20
7–8	20–40
>8	30–50

Reproduced with permission from Brewster DC, Cronenwett JL, Hallett JW Jr, et al. Guidelines for the treatment of abdominal aortic aneurysms. Report of a subcommittee of the Joint Council of the American Association for Vascular Surgery and Society for Vascular Surgery. *J Vasc Surg* 2003;37:1106–1117.

4 The natural history of AAAs is to increase in size. The reported mean rate of growth has varied from 0.2 to 0.3 cm/yr in population studies^{57–59} to 0.4 cm/yr from referral practices^{60–62} with the latter figure (0.4 cm/yr) generally quoted as a reasonable estimate. Several factors including female gender, current smoking, and larger original diameter have been associated with an increased rate of growth as might be predicted from the risk factors for rupture.^{57,59,63} Interestingly, early studies showed that doxycycline and coenzyme A reductase inhibitors (i.e., statins) may inhibit aneurysm growth. More recent literature has shown promise for statins inhibiting growth and rupture of AAA; however, doxycycline has been proven ineffective in a randomized trial.^{63–67} It should be emphasized that these growth rates are mean values and that aneurysms do not always grow in a linear fashion, as might be predicted. The growth curve may be somewhat erratic or “staccato” with no growth detected during consecutive 6-month intervals followed by a growth of 0.6 cm during the next follow-up interval.⁶⁸ Furthermore, it should be emphasized that the past rate of growth does not predict future growth; patients should not be lulled into a false sense of security if their aneurysm is relatively stable over time, and should be encouraged to continue monitoring with a vascular specialist.

The mortality rate associated with repair of an AAA depends on the status of the aneurysm (intact/asymptomatic, intact/symptomatic, ruptured), the physiologic state of the patient (age and

medical comorbidities), and the method of repair (open vs. endovascular). Population studies from Medicare and the Nationwide Inpatient Sample (NIS) have reported that operative mortality rates for *open repair of intact* aneurysms in the United States range from 4.2% to 5.4% over the past decade.³⁴ Predictably, the operative mortality rate increases with age, ranging from 2.2% among persons of 50 to 59 years of age to 9.2% among those >80. Interestingly, operative mortality rate has been shown to be significantly higher among women (6.1% vs. 3.7%). The mortality rate for open repair in the randomized trials comparing operative repair with surveillance for small aneurysms (UK Small Aneurysm Trial – 5.8%, ADAM – 2.7%) and open repair with endovascular repair (DREAM – 4.6%, EVAR Trial – 4.6%)^{69,70} are within the range of these nationwide series. Furthermore, a literature review examining the mortality rate of open AAA repair encompassing 64 individual studies reported a collective rate of 5.5%.⁷¹

The reported operative mortality rate for *endovascular repair of intact* AAAs has been consistently less than those for the open approach.^{72–78} Schermerhorn et al.⁷⁴ reported that the operative mortality after endovascular aneurysm repair (EVAR) was 1.2% among Medicare beneficiaries during 2001 to 2004 while mortality within the NIS through 2005 was 1.3%. Results from the Dutch Randomized Endovascular Aneurysm Management (DREAM) Trial⁷⁰ and the Endovascular Aneurysm (EVAR) Trial⁷⁹ comparing open and endovascular repair have reported that the perioperative mortality rate is lower for endovascular repair and within the same range (DREAM – 1.2% vs. 4.6%; EVAR Trial – 1.7% vs. 4.7%).

The operative mortality rate for *open repair of intact/symptomatic* aneurysms among patients undergoing emergent repair exceeds that for elective repair and has ranged from 9% to 19%.^{13,80,81} Various explanations have been proposed for this increased mortality rate relative to that for intact/asymptomatic aneurysms including failure to maximize preoperative medical conditions, increased incidence of inadvertent venous injuries, and less experienced operative teams, although the true explanation remains unclear. However, in more recent data, De Martino et al.⁸² reported from the Vascular Study Group of Northern New England a perioperative mortality of 2.1% and 0% for open and endovascular repair for intact/symptomatic aneurysms, respectively. However, late mortality and in-hospital adverse events were still higher comparable to the asymptomatic cohort.

5 6 The actual mortality rate for ruptured AAAs is somewhat difficult to determine because a significant number of sudden deaths in elderly patients are likely secondary to ruptured aneurysms. It has been estimated that 50% of all patients with ruptured AAAs die outside the hospital, and that approximately 50% of those who actually undergo open repair do not survive.¹³ Indeed, a meta-analysis spanning 50 years and 77 studies reported that the operative mortality rate for the *open repair of ruptured* aneurysms was 48%.⁸³ These figures correspond to an overall mortality rate of approximately 80% although this may be an underestimate. It is remarkable that the optimization of pre-hospital and emergency room care including a reduction in the mean transfer time from the emergency department to the operating room to 12 minutes did not appear to result in a decrease of the mortality rate of ruptured aneurysms.⁸⁴ Notably, the operative mortality rate for ruptured aneurysms treated with the open approach has improved slightly over the past few decades with Bown et al.⁸³ reporting a 3.5% reduction per decade.

The mortality rate for the *endovascular repair of ruptured* AAAs is lower than associated with the open approach, although data may be significantly skewed by selection bias.^{19,85–91} Rayt et al.⁸⁸ reported a collective mortality rate of 24% for the endovascular approach from 31 studies encompassing 982 patients while other meta-analyses or systematic reviews have reported comparable rates.^{86,89} The potential to treat ruptured AAAs with the endovascular approach may represent the greatest contribution or benefit of the technology. However, further validation is necessary since the reports cited above likely reflect both patient selection and publication bias. In population data, Giles et al.⁹¹ and Schermerhorn et al.¹⁹ reported that the annual number of deaths across the country from both intact and ruptured aneurysms has decreased significantly since the introduction of EVAR.

CLINICAL PRESENTATION AND DIAGNOSIS

7 The overwhelming majority of AAAs are asymptomatic at the time of discovery. Most aneurysms are detected by abdominal or pelvic imaging studies, such as ultrasonography and CT, performed for other indications (e.g., chronic back pain, renal cysts) rather than on physical examination. Indeed, it is often difficult to palpate an AAA on physical examination because of its anatomic location in the posterior abdomen adjacent to the spine and these difficulties are exacerbated in the presence of truncal obesity. A literature review examining the accuracy of physical examination reported that the sensitivity ranged

from 33% to 100%, the specificity ranged from 75% to 100%, and the positive predictive value ranged from 14% to 100%.⁹² Given these fairly broad ranges, the authors concluded that physical examination could not be relied upon to exclude an AAA. Predictably, the accuracy of primary care physicians for detecting an AAA in patients with known aneurysms is only fair because of the limitations noted above and the failure to actually palpate the aorta during the physical examination. Intact abdominal aortic and iliac artery aneurysms may present with symptoms that lead to further investigation and the correct diagnosis although this is the exception rather than the rule. Rarely, enlargement of the aneurysm may cause vertebral erosion and chronic back pain. In addition, thrombosis of an AAA may cause acute ischemia in the lower torso, and aneurysms may be a source of arterial macroemboli or microemboli leading to acute ischemia of a lower extremity or digit, respectively.

Patients with intact/symptomatic or ruptured aneurysms present with abdominal or back pain related to the aneurysm itself. The character of the pain is variable and ranges from dull to sharp. The pain is usually acute in onset and persistent. It may be superimposed on more chronic abdominal or back pain, but the presentation is usually not subtle, and the pain can be differentiated from more chronic complaints. In addition, the pain may radiate from the abdomen to the back, flank, inguinal region, or genitalia. Approximately 10% of patients with ruptured AAAs present with signs and symptoms similar to those of ureteral colic or other acute urologic problems.⁹³ For example, the diagnosis of a ruptured aneurysm must be ruled out in a timely fashion in patients who might be at risk for AAA presenting with testicular pain who have a normal urinalysis and testicular examination.

Patients with a ruptured AAA may present anywhere along the spectrum from hemodynamically normal to profound shock. Their status depends on the ability of the tissues adjacent to the aorta to tamponade the bleeding. If the adjacent tissues effectively contain the bleeding, the patient may present in a hemodynamically stable state with essentially normal vital signs. However, it should be emphasized that this is usually a temporary situation, and health care providers should not be lulled into a false sense of security. A ruptured AAA is a true medical emergency that requires immediate operative repair regardless of the patient's hemodynamic status. Tamponade can quickly degenerate into free intraperitoneal rupture and exsanguinating hemorrhage. Furthermore, vital signs may be misleading because patients can lose up to 15% of their blood volume (class 1 shock) without any appreciable change in their pulse rate or blood pressure. If the aneurysm initially ruptures freely into the peritoneal space, patients usually exsanguinate before they can seek medical attention.

Patients with a ruptured AAA may also present with either an aortoenteric or an aortocaval fistula, although both are relatively rare. Patients with an aortoenteric fistula may present with massive intestinal bleeding, but often present with a "sentinel" bleed that is small volume. The aorta may rupture through any portion of the bowel, although the duodenum and proximal small bowel are the most common sites. The overwhelming majority of aortoenteric fistulae result from the erosion of a prosthetic graft into the adjacent bowel (secondary aortoenteric fistula) rather than from an unrepaired aneurysm (primary aortoenteric fistula). The diagnosis of an aortoenteric fistula must be ruled out in all patients with gastrointestinal bleeding and either an AAA or a previous infrarenal aortic reconstruction. Patients with an aortocaval fistula generally present with high-output congestive heart failure, a continuous abdominal bruit, and edema of the lower extremities. The severity of the heart failure symptoms depends on the size of the fistula and the magnitude of the systemic shunt.

8 Several imaging studies are available to establish or confirm the diagnosis of an AAA. Indeed, the introduction of endovascular techniques for aneurysm repair has resulted in an evolution of these modalities. The generic imaging goals for patients with an AAA are to establish the diagnosis, determine the presence of rupture, determine the cephalad/caudal extent of the aneurysm, determine the feasibility of endovascular repair, appropriately size the aneurysm and access vessels for endovascular repair, screen for other visceral pathology, and screen for the presence of anatomic variants that would complicate operative repair, such as a left-sided vena cava or a horseshoe kidney. Although no imaging study satisfies every objective, ultrasound has emerged as the ideal *screening* study with CT arteriography being the definitive *diagnostic* test and the preferred modality for operative planning.

Abdominal ultrasound is a safe, simple, and inexpensive means of detecting AAAs (Fig. 96-3). It is relatively inexpensive and does not require the use of ionizing radiation or intravenous contrast. Furthermore, ultrasound units are portable and almost universally available in the hospital setting including the emergency room.⁹⁴ The sensitivity of ultrasound for detecting AAAs is acceptable, and the technique is reproducible within 0.3 cm in experienced hands.⁹⁵ However, the technique is quite operator-dependent and potentially confounded by the presence of bowel gas or extreme obesity. Ultrasound can accurately image the infrarenal aorta to its bifurcation but is less reliable for imaging

the portions of the aorta proximal to the renal arteries and distal to the iliac vessels. Furthermore, it is not as reliable as CT for differentiating a ruptured from an intact aneurysm. However, ultrasound is an excellent tool for screening patients at high risk for an AAA and for confirming the presence of an aneurysm suspected by physical examination or clinical presentation. Further, it is a useful technique to follow patients with small aneurysms (< 4 cm) when the exact measurement is not crucial. It should not be used to confirm the diagnosis of a ruptured aneurysm, nor should it be used as the sole imaging study before elective repair because it does not provide a complete image of the aorta and iliac arteries.

Figure 96-3. B-mode ultrasound image showing a transverse view of an infrarenal abdominal aortic aneurysm. Note the vessel wall and the large quantity of intraluminal clot surrounding the smaller, blood-filled center (*dark circle*).

CT arteriography overcomes many of the limitations of ultrasound and represents the current “gold standard” for imaging patients with AAAs (Fig. 96-4). The downside of CT is the greater expense and the potential harm that may be caused by the requisite ionizing radiation and intravenous contrast. Indeed, the evolution of EVAR and the required follow-up imaging studies have focused increased attention on the magnitude of long-term radiation injury. It is worth noting that the radiation dose associated with an abdominopelvic CT scan is 10 to 20 mGy while that for a routine chest radiograph is only 0.5 mGy. The incidence of allergic reactions to the contrast may be reduced by a steroid preparation while the potential nephrotoxicity can be reduced by acetylcysteine or sodium bicarbonate.^{96,97} Of course, the renal risks can be avoided altogether by not using contrast. However, the quality of the noncontrast images is less than optimal, and is generally not useful for determining eligibility for endovascular repair. CT is very sensitive for detecting both intact and ruptured aneurysms, and the images are reproducible within 0.2 cm.⁹⁵ The quality of the CT images has continued to improve with each new generation of scanners, and the image acquisition times have decreased. Currently, CT imaging of the arterial tree from the ascending aorta to the femoral arteries can be obtained with an image acquisition time of less than 45 seconds. Given the quality and ease of imaging, CT arteriograms have essentially replaced traditional catheter-based diagnostic arteriograms for evaluation of aneurysms. Using axial CT images and 3D imaging software, a 3D image of the aorta can be obtained that allows measurements along the centerline of blood flow (Fig. 96-5), and dramatically improve the accuracy and consistency of sizing for endovascular repair.⁹⁸ CT is also helpful for detecting other intra-abdominal pathology or anatomic variants that may impact the operative approach. Specific concerns include the location of the left renal vein and other associated venous anomalies, the location and size of the kidneys, and the characteristics of the aneurysm wall. CT is currently the sole diagnostic test performed before repair in the majority of cases and the imaging study of choice to confirm or refute the diagnosis of a ruptured AAA. In addition, CT is the serial imaging study of choice when aneurysms exceed 4 cm and approach the threshold for intervention.

Figure 96-4. CT scan demonstrates a large abdominal aortic aneurysm. Note that the majority of the lumen is filled with contrast.

Figure 96-5. 3D CT of the aorta and the iliac, femoral, and visceral arteries is shown. Note the infrarenal abdominal aortic aneurysm that extends to the aortic bifurcation.

Both magnetic resonance imaging (MRI) and catheter-based arteriography have been used as diagnostic imaging studies for patients with AAAs. The image quality and overall sensitivity of MRI is comparable to CT, but the technology is not as widely available and most surgeons are less familiar with interpreting the images. Furthermore, the technique is relatively contraindicated for patients with ferromagnetic devices (e.g., pacemakers, joints) or renal insufficiency, and imaging critically ill patients is cumbersome, if not prohibitive.

Importantly, aneurysms are frequently diagnosed during catheter-based arteriography performed for other purposes, but this should not be viewed as a diagnostic test of choice for AAAs. An arteriogram only delineates the lumen of the vessels (i.e., aorta, iliac and femoral arteries), and thus gives no indication of aneurysm extent or diameter. AAAs are often filled with laminated thrombus and may have a relatively normal appearing lumen. The “lumenogram” produced by the contrast reflects the patent lumen rather than the “true” lumen of the vessel (and the actual cross-sectional diameter of the aneurysm).

The diagnostic approach and initial treatment for patients with a potential ruptured aneurysm merit further comment. Because of the high attendant mortality rate, prompt diagnosis and repair are necessary. In a study from the Cleveland Clinic Vascular Registry, the operative mortality rate associated with ruptured AAAs increased from 35% when the initial diagnosis was correct to 75% when

incorrect.⁹⁹ Admittedly, the clinical presentation may be confusing, and delays in diagnosis are not uncommon. The classic triad of hypotension, abdominal pain, and a pulsatile abdominal mass was present in only 50% of patients with ruptured aneurysms in a single institutional series.¹⁰⁰

Elderly patients who present to the emergency room in a hemodynamically *unstable* state with abdominal or back pain can often be evaluated quickly in the emergency department with ultrasound or CTA if they are stable enough for the examination. The potential causes of shock (i.e., hypovolemic, cardiogenic, septic, neurogenic) can usually be quickly differentiated by a brief history and physical examination. However, this clinical scenario is most suggestive of hypovolemic or hemorrhagic shock resulting from an intra-abdominal catastrophe. The differential diagnosis is extensive and includes pancreatitis, mesenteric infarction, acute Addisonian crisis, and rupture of a visceral artery aneurysm in addition to rupture of an AAA. A myocardial infarction can mimic a ruptured aneurysm in this patient population and potentially confounds the diagnosis, although it can usually be confirmed by the findings on electrocardiogram. Additional diagnostic imaging has not traditionally been considered necessary in this setting and, indeed, has been considered potentially harmful due to the obligatory delay in getting patients to the operating room. Due to the dramatic reduction in CT acquisition times and the potential feasibility of endovascular repair, abdominal/pelvic CT scans are allowable in this scenario to confirm the diagnosis and plan the operative procedure, provided it can be performed expeditiously. This approach has the added advantage of reducing the number of negative abdominal explorations in critically ill patients. A natural history study of patients with ruptured AAAs not offered operative repair reported that <15% of the patients died within 2 hours of hospital admission.¹⁰¹ Based upon these findings, the authors concluded that most patients with ruptured aneurysms are sufficiently stable to undergo a CT scan and this opinion has been supported by improved mortality results of EVAR for ruptured aneurysms.⁸⁹

Several findings on CT are suggestive of a ruptured AAA including disruption of the calcium ring within the aortic wall, disruption of the aortic margins, retroperitoneal hematomas, mass lesions in the psoas region, displacement of the kidneys, abnormal soft tissues posterior to the aorta, effacement of the normal fat planes between the aorta and adjacent viscera, and abnormal retroperitoneal fluid collections (Fig. 96-6). Patients undergoing an emergent CT arteriogram to rule out a ruptured AAA should not receive oral contrast because of the delay associated with its administration and the confounding effects on the imaging of the vessels.

Figure 96-6. Contrast CT demonstrates a ruptured abdominal aortic aneurysm. Note the large retroperitoneal hematoma and the loss of the normal fat plane anterior and lateral to the left psoas muscle.

The diagnosis of a ruptured AAA should be considered in elderly patients that present to the emergency room hemodynamically *stable* with abdominal or back pain. Admittedly, the differential diagnosis for abdominal or back pain in this patient population is extensive, and the incidence of a ruptured AAA is small. An expeditious history and physical examination can usually determine the cause of the pain. A pulsatile abdominal aortic mass, an unexplained low hematocrit, or hemodynamic instability before presentation are particularly worrisome and increase the level of suspicion. The diagnosis of an AAA may be confirmed with a portable abdominal ultrasound in the emergency room.⁹⁴ Indeed, the current trauma algorithms include abdominal ultrasound as a diagnostic technique for blunt trauma, and many centers have ultrasound units assigned to the emergency room and personnel who are

appropriately trained. If ultrasound confirms the diagnosis of an aneurysm, further evaluation with CT should be obtained to rule out rupture. Alternatively, a CT may be obtained as the sole imaging study. Any findings consistent with a ruptured aneurysm on CT mandate direct transfer to the operating room and immediate repair. Aggressive fluid resuscitation should be avoided and mild hypotension (i.e., systolic pressure >80 mm Hg) tolerated in conscious patients due to the theoretical potential to cause the aneurysm to rupture into the peritoneal cavity and/or release the tamponade effect of the retroperitoneal tissue. If an intact aneurysm is found on CT without any suggestion of rupture, the next logical question is whether the aneurysm is the source of the pain. Symptomatic aneurysms are likely associated with an increased risk of rupture although the natural history remains poorly defined. Patients with symptomatic/intact aneurysms ≥ 5 cm in diameter should be admitted to a monitored setting and scheduled for urgent operative repair, usually the following day, provided no alternative causes for the pain are identified. Additional sources of the abdominal pain should be sought in patients with aneurysms smaller than 4 cm in light of the small rupture risk. The appropriate treatment for patients with aneurysms 4 to 5 cm is less clear. These aneurysms have the potential to rupture although the risk is small. It is recommended that these patients be admitted and the source of their pain further investigated. However, urgent operative repair is recommended if no additional causes are identified.

The role of screening for AAAs in asymptomatic patients has been partially clarified. The United States Preventative Task Force has issued a position statement advocating a single screening ultrasound in males 65 to 75 years of age who have a smoking history and selective screening for males without smoking history.¹⁰² These recommendations were based upon the results of a best-evidence systematic review that identified four population-based randomized controlled trials demonstrating that screening resulted in a reduction of aneurysm-related mortality.¹⁰³ Notably, the Preventative Task Force stated that the literature did not substantiate screening for women even among those who smoke or have a family history and stated that the harms of screening outweighed the risks for screening women who have never smoked. Screening for AAAs in this subset of elderly men has been shown to be both cost effective¹⁰⁴ and comparable to other screening programs in adult patients.¹⁰⁵ Despite the Preventative Task Force's recommendations, screening should likely be extended to other high-risk patient populations including patients with a first-degree relative with an AAA, evidence of a peripheral artery aneurysm, and those undergoing evaluation for heart transplantation. Medicare currently pays for a single screening ultrasound as part of the Welcome to Medicare physical examination for men who have smoked sometime during their life and for both men and women with a family history of AAAs.

OPERATIVE INDICATIONS

All patients with symptomatic or ruptured AAAs should undergo operative repair unless they have an underlying medical condition, such as metastatic cancer, that precludes long-term survival or their quality of life is not sufficient to justify the intervention. The latter situation entails a difficult decision, but not offering operative repair should be considered in certain cases (e.g., a debilitated, demented patient in a nursing home) after discussion with the patient if he or she is alert and coherent and with the patient's family.

The operative decision-making process for intact/asymptomatic AAAs is a complex one that needs to be tailored to the individual patient. Indeed, there is no single parameter that merits repair. The operative indications are contingent upon the size of the aneurysm, life expectancy, comorbidities, preference, and anatomic configuration. It is important to remember that the repair of an intact/asymptomatic AAA is a prophylactic operation that represents a balance between the operative risk and the future risk of rupture with the ultimate treatment goals to prolong life, relieve symptoms, and prevent rupture.

The diameter of the AAA is the best predictor of rupture as stated above and has been used as the most common indication for repair. There has been a change in the diameter-based operative criteria within the past few decades although this has been clarified more recently with level 1 evidence. It is interesting to note that the diameter threshold for good-risk patients has decreased from 6 cm to as low as 4 cm with latter recommendation from the guidelines of the national vascular surgical societies.⁹⁵ Both the UK Small Aneurysm Trial⁴⁹ and the ADAM Trial³⁵ concluded that it was safe to follow patients with 4- to 5.5-cm aneurysms and that early operation did not confer any long-term survival benefit. As noted above, the rupture risk for patients in the surveillance group was <1%/yr. It is important to note that more than 60% of the patients in both studies ultimately underwent operative repair despite their initial randomization. A longer-term follow-up study from the UK Small Aneurysm Trial extending to 12

years did not demonstrate a survival benefit for the patients assigned to early surgery.¹⁰⁶ However, it is important to note that almost all of the patients that survived ultimately required repair since their aneurysms continued to grow and exceed the 5.5-cm threshold. Indeed, the relevant question may not be whether patients with small aneurysm need to be repaired, but rather when they need to be repaired. In a separate publication from the UK Small Aneurysm Trial, Brown et al.⁵⁰ reported that the rupture risk for women was over 4-fold higher, as noted above, suggesting that the 5.5-cm diameter threshold for repair may be too high for women. The proponents of smaller diameter-based thresholds for repair (i.e., <5.5 cm) have justified their approach stating that even small aneurysms rupture, aneurysms continue to increase in diameter and will likely need to be repaired, the patients' medical conditions will likely deteriorate with age, and the operative mortality/morbidity rate for small aneurysms may be less. Although the level 1 evidence does not support this lower threshold, it is important to note that the size discrepancy between a 5.2-cm and a 5.5-cm aneurysm is very small and likely within the resolution of the imaging study.

The presence of medical comorbidities predictably impacts the perioperative mortality rate and threshold for repair. Steyerberg et al.¹⁰⁷ identified several independent risk factors for operative mortality during open repair, including renal insufficiency (creatinine >1.8 mg/dL, congestive heart failure, ECG ischemia, pulmonary dysfunction, older age, and female gender) and these have remained consistent throughout the literature. Similarly, Beck et al.⁷² developed a predictive model for both open and endovascular repair using a prospective registry from the Vascular Study Group of New England. They reported that chronic obstructive pulmonary disease, suprarenal aortic clamp, renal insufficiency and advanced age (≥ 70) were predictive of mortality at 1 year after open repair with the mortality ranging from 1% to 67% depending upon the number of risk factors. Congestive heart failure and larger aneurysm diameter (≥ 6.5 cm) were the only predictive factors after endovascular repair with the mortality ranging from 4% to 23%. The consistent, dramatic impact of renal insufficiency was further emphasized by a national series that reported a 9-fold increase in mortality. Notably, the estimated glomerular filtration rate may be a better index of renal function than serum creatinine and, therefore, likely a better predictor of adverse outcome. Life expectancy is inseparable from comorbidities, but it should be emphasized that the average life expectancy for a 60-year-old and an 85-year-old man in the United States is 18 and 5 years, respectively.¹⁰⁸

Patient preference should be factored into the operative decision process. Although the level 1 evidence suggests that it is safe to follow AAAs until they reach the 5.5-cm threshold, patients may not be willing to accept this small, finite risk and desire to have their aneurysm repaired at a lower threshold. Indeed, patients often echo the justification for early repair proposed by surgeons.

The anatomic configuration of the aneurysm and/or the associated structures should factor into the operative decision process as well. Any technical factors that complicate the repair likely increase the perioperative mortality/morbidity including the need for suprarenal clamp application due to the obligatory renal/visceral ischemia, venous anomalies (e.g., left-sided vena cava), renal anomalies (e.g., horseshoe kidney), and inflammatory aneurysms. Admittedly, many of these technical concerns are relevant only to the open approach and can be overcome/avoided by endovascular repair provided that it is an option from an anatomic standpoint. Anatomic concerns relevant to endovascular repair include continued aneurysm degeneration of the aortic neck or iliac arteries that may make standard infrarenal endograft repair more difficult or impossible unless early repair is undertaken.
